Subject: Re: SUPPORT Analyses

Hi Rose
Obviously we did not do a good job in defining when and how to define Oxygen dependency and what oximeter to use. I believe that the results are still OK as the majority used conventional oximeters and I believe that any bias would have been balanced for those that used study oximeters.
If we were reporting a significant difference then we would need to be more concerned - as things stand I doubt that the direction of change would be changed. We can do analyses comparing BPD using both definitions comparing the site practices - ie compare the 11 sites using a conventional oximeter with the remaining ones and see if there is any major difference The majority did as we intended - they used clinical oximeters for both.
All the best for the Holidays
Neil

Subject: RE: SUPPORT Analyses
Date: Wednesday, December 23, 2009 9:52:00 AM
Attachments: Oximeter.xls

Here are the results from the oximeter questions - Iowa answer is mixed depending on the location of the infant. There were 3 sites that challenged using the study oximeter according to these results. Perhaps we should look at the Phys def forms and see if the sites recorded Masimo on the form (as we asked which oximeter was used for the challenge.

For the BPD def - we could look at the individual cases to see exactly how much oxygen the children were on.

Let me know what you think

Rose

Subject: SUPPORT Analyses

Hello Everyone
I would now like to have more analyses for the SpO2 study. I want to see the actual FiO2 requirements for the infants during the first 2 weeks, and later. We can do a survival type analysis and I will leave that to Marie to figure out
The study was designed to separate the infants by oxygen exposure and now we need to know how well we achieved this with the study POs.
In addition we need to start looking at the actual durations of SpO2 < 80 and > 96% as well as durations below 75%, < 70%, <60 and < 50% as durations comparing low and hi groups.
We may want these to respond to any questions form reviewers
Thanks Marie for running these.
Be well
Neil

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

For SUPPORT, the manual states:

The study pulse oximeters will be applied to the infant within two hours following NICU admission. The assigned PO will remain on the infant and will be removed once the infant has been in room air and off ventilatory support or CPAP for 72 hours, and if oxygen is subsequently required a similar altered pulse oximeter providing the same SpO2 range will be used until 36 weeks PCA.

For determination of eligibility for the challenge, did you determine eligibility using:

_____ Study oximeter

___X__ Clinical oximeter

If a challenge occurred, did your site use

_____Study Oximeter

___X__Clinical oximeter

For BPD by oxygen definition, did you use:

_____ Study oximeter

___X__ Clinical oximeter

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Dear Dr Zaterka-Baxter

I have been in touch with Professor William Fraser, chair of the Data monitoring Committee for the COT trial. We would both find it helpful to have an indication of the envisaged timing of the publication of the short term results of the SUPPORT trial, which you kindly sent to us in confidence. Can you help us, please?

Yours sincerely

Iain Chalmers

Subject: Re: ROP missing outcomes for SUPPORT

Importance: High

I would hold these until we have word about manuscript decisions. We can add these results at that time More importantly, how do these effect the statistics for the ROP outcomes. Can we have these run and se what the new results are?

Thanks
Neil

If there were predefined secondary analyses in the protocol, this may be ok. If not (or vague) we should probably have a clear analysis plan prior to moving thid along. What do you think??

Hello Everyone
I understand that you want to wait and see what the journal weants. However, I want these analyses as they are essential in understanding what we found. I have not seen any FiO2 data as yet and this was the purpose of the oximeters. That is the reason for the oximeter separation and we have not even proven as we did for the initial DSMC stoppage that there was a separation.
Please let me know if you do not want these and why.
Otherwise, can we get started looking at these?
Thanks
Neil
Principal Investigator (I think!!)

Hi Everyone
I would like to ask that we run the following in anticipation of any reviewers questions
I would like to see an FiO2 analysis – ie the actual difference in FiO2 by day for the first 14 days between the 2 SpO2 groups, and after 14 days
The oximeters were designed to separate the actual FiO2 exposure of these 2 groups.
In addition I would like an analysis of the SpO2 durations of < 80% > 96% and durations of SpO2 < 75%, < 70% < 60% and < 50% for the 2 groups. I suspect this may be helpful in looking at the exposure to severe hypoxia.
Marie can you begin these??
All the best for Christmas and the New Year to everyone and thanks again for a great job!!!!!
Thanks
Neil

Subject: Physiologic Def for SUPPORT infants
Importance: High

For SUPPORT, the manual states:
The study pulse oximeters will be applied to the infant within two hours following NICU admission. The
assigned PO will remain on the infant and will be removed once the infant has been in room air and off
ventilatory support or CPAP for 72 hours, and if oxygen is subsequently required a similar altered pulse
oximeter providing the same SpO2 range will be used until 36 weeks PCA.

For determination of eligibility for the challenge, did you determine eligibility using:
___ X __ Study oximeter
___ X _ Clinical oximeter 5 patients

If a challenge occurred, did your site use
__ X ___Study Oximeter
__ X __Clinical oximeter 1 patient

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

For BPD by oxygen definition, did you use:

X Study oximeter

X Clinical oximeter 1 patient

Let me know by Dec. 17

Thanks

From: Sood, Beena
To: Higgins, Rosemary (NIH/NICHD) [E]
Cc: Shankaran, Seetha; Bara, Rebecca
Subject: RE: Physiologic Def for SUPPORT infants
Date: Wednesday, December 16, 2009 10:45:40 AM

Dr Higgins,
At WSU, we used clinical oximeters – Becky has described the procedure we followed below:

"If our SUPPORT infants were on study oximeters at 36 weeks 0 days (still on oxygen), the study oximeters were removed at just about midday and replaced with clinical oximeters. Challenge criteria were then based on oxygen sats documented the rest of that day and the midnight hours of 36 weeks 1 day. Documentation of oxygen saturations using an unaltered oximeter is the only way to determine a baby's true eligibility. So...

In determining the physiologic definition of BPD eligibility (challenge criteria) we used clinical oximeters. If a challenge occurred, it was done using a clinical oximeter."

Let me know if there are any other questions

Thanks
Beena

Subject: Physiologic Def for SUPPORT infants
Importance: High

For SUPPORT, the manual states:
The study pulse oximeters will be applied to the infant within two hours following NICU admission. The
assigned PO will remain on the infant and will be removed once the infant has been in room air and off
ventilatory support or CPAP for 72 hours, and if oxygen is subsequently required a similar altered pulse
oximeter providing the same SpO2 range will be used until 36 weeks PCA.

For determination of eligibility for the challenge, did you determine eligibility using:
_____ Study oximeter
_____ Clinical oximeter

If a challenge occurred, did your site use
_____Study Oximeter
_____Clinical oximeter

Let me know by Dec. 17

Thanks
Rose

Dr. Higgins
The study oximeter was used to determine eligibility for the challenge (for those that were still on the study oximeter at 36 weeks) and was also used for the challenge.

Thanks
Kim

Subject: Re: Physiologic Def for SUPPORT infants

Dr. Higgins,
The PHYO2BASE form, Question A.2. asks what type of oximeter is used in the challenge. The answer in that field may be helpful. If it says anything other than "Masimo" it was not a study oximeter. If it says Masimo you would need to know if the center used Masimo monitors clinically. New Mexico does not.
Just a thought,
Connie

Subject: Re: Physiologic Def for SUPPORT infants

Dr. Higgins,
In New Mexico the Study oximeter was kept on the patient until 36 weeks, death, transfer, or room air. Therefore, the study oximeter was used to determine eligibility for RA challenge, and to record the use of oxygen at 36 weeks. As you can see from the attached table, 16 subjects were alive at 36 weeks. Four of those were on clinical oximeters because they were in another hospital. One more was on a clinical oximeter because they were in room air. Of the 4 on whom the challenge was done, 3 were still on the study oximeter at the time of the challenge. One challenge was done on a clinical oximeter because it was done after the 36 weeks date, but the subject had been on the study oximeter at 36 weeks.
I hope this answers your questions.
Connie

For SUPPORT, the manual states:
The study pulse oximeters will be applied to the infant within two hours following NICU admission. The assigned PO will remain on the infant and will be removed once the infant has been in room air and off ventilatory support or CPAP for 72 hours, and if oxygen is subsequently required a similar altered pulse oximeter providing the same SpO2 range will be used until 36 weeks PCA.

For determination of eligibility for the challenge, did you determine eligibility using:
_____ Study oximeter

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

_____ Clinical oximeter

If a challenge occurred, did your site use
_____Study Oximeter
_____Clinical oximeter

Let me know by Dec. 17

Thanks
Rose

Yes, it was 68. Infant was originally at 2 LPM with an FiO2 of .21 and when the flow was turned down to 0.5 LPM that's when the sats plunged.

Rose,
I looked at the completed PHY02BASE forms for our SUPPORT babies who had challenges. According to my records one of our infants was tested with a Masimo (not sure why or how it happened). All of the other infants had clinical oximeters used for eligibility, the challenge, and for BPD by oxygen definition. The infant, who had the Masimo in place, failed when the sats went to 68 so the outcome would have been the same with a clinical oximeter.
Hope this answers your questions.
Thanks,
Nancy

At UAB, determination of eligibility by study pulse oximeter used on 36 week PCA day. If infant had challenge done, it was done with a clinical pulse oximeter.
Study PO left on baby on day 36 week because 4 data points were required on that day. After the study PO was removed, the infant, if requiring challenge, had a 5 minute period of baseline on a clinical PO, and then the challenge was done.
Monica

Subject: RE: Physiologic Def for SUPPORT infants

Rose,
We followed the manual guidelines for use of the study oximeters – so any baby on oxygen indeed was still on a study oximeter up until 36 weeks. We determined if babies were eligible for a challenge at 36 weeks – then notified the study RT that a challenge needed to be performed sometime in the next week. So, in general, all challenges would be performed on a clinical oximeters because the study oximeters was removed at 36 weeks and the challenge occurred in that next week after 36 weeks. What we don't know for sure is how efficient the RTs were in doing the challenge – in general, I think it is fair to say that babies would have all been on clinical oximeters – but could there have been a few babies here or there that the challenge was done on the same exact day that the baby hit 36 weeks and maybe the study oximeters was still on – possibly – but I really don't think we were that speedy in getting the challenges done exactly on the day the baby hit 36 weeks but we were efficient at removing the study oximeters on exactly that day. Clear as mud? I don't think any of the SUPPORT forms ask for the exact day the challenge was done, did they? Let us know if this doesn't make sense. Brenda and Leslie

Subject: Physiologic Def for SUPPORT infants
Importance: High

For SUPPORT, the manual states:
The study pulse oximeters will be applied to the infant within two hours following NICU admission. The
assigned PO will remain on the infant and will be removed once the infant has been in room air and off
ventilatory support or CPAP for 72 hours, and if oxygen is subsequently required a similar altered pulse
oximeter providing the same SpO2 range will be used until 36 weeks PCA.

For determination of eligibility for the challenge, did you determine eligibility using:
_____ Study oximeter
_____ Clinical oximeter

If a challenge occurred, did your site use
_____Study Oximeter
_____Clinical oximeter

Let me know by Dec. 17

Thanks
Rose

Rose,
Our answer is mixed. Some of the kids moved up to the extension unit, where we weren't allowed to use the study oximeters (they didn't speak to the central alarm system). So, some were on the study ox and others on the clinical one. If you need me to send specifics, I can.

Subject: Physiologic Def for SUPPORT infants
Importance: High

For SUPPORT, the manual states:
The study pulse oximeters will be applied to the infant within two hours following NICU admission. The
assigned PO will remain on the infant and will be removed once the infant has been in room air and off
ventilatory support or CPAP for 72 hours, and if oxygen is subsequently required a similar altered pulse
oximeter providing the same SpO2 range will be used until 36 weeks PCA.

For determination of eligibility for the challenge, did you determine eligibility using:
_____ Study oximeter
_____ Clinical oximeter

If a challenge occurred, did your site use
_____Study Oximeter
_____Clinical oximeter

Let me know by Dec. 17

Subject: Breathing Outcome Questions

Rose,

My understanding is that our group previously asked you if we could use the SUPPORT breathing outcome questions for another NIH-funded study that our Chief of Newborn Medicine, Dr. Jonathan Davis, is heading and that this permission had been granted.

The study sites need to submit these questions to the IRB. We want to make sure that you are aware that this study will start very soon with the plan to use the SUPPORT questions and that you don't have any new found concerns.

The purpose of Dr. Davis' study is to find better ways to predict long-term breathing outcomes in infants who were born very premature and to then use these predictors in future research studies that look at treatments to prevent respiratory problems.

Please confirm we can move forward using the breathing outcome questions.

Thanks,
Anne

Dear Dr. Finer and co-authors,

Thank you for submitting your manuscript, "Early CPAP versus Surfactant in Very Preterm Infants: The SUPPORT Trial" to the New England Journal of Medicine.

Your manuscript has been forwarded to members of our editorial staff, who will make an initial evaluation and decide whether it merits further consideration. You will be notified of the decision as soon as possible.

Your manuscript ID is 09-11783.

Please mention the above manuscript ID in all future correspondence or when calling the office for questions. If there are any changes in your street address or e-mail address, please log in to Manuscript Central at http://mc05.manuscriptcentral.com/nejm and edit your user information as appropriate. You may also view the status of your manuscript at any time by checking For Authors section of the site.

We are undertaking evaluation of your manuscript with the understanding that neither the substance of the article nor the figures or tables have been published or will be submitted for publication elsewhere during the period of review.

Please provide the editors with copies of other manuscripts by you or your coauthors addressing similar or related research questions that are in preparation or under consideration at other journals. This does not apply to abstracts published in connection with scientific meetings or to news reports based on presentations at such meetings.

The Journal's policy is explained more fully at http://www.nejm.org/hfa/policies.asp.

Please call us at 617-734-9800 if you have any questions.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Sincerely,

Jeffrey M. Drazen, M.D.

Subject: RE: Confidential SUPPORT papers for submission to NEJM
Date: Wednesday, December 02, 2009 12:02:07 PM

Rose,
Nicely done. Please let us know if this is accepted by NEJM—it would be nice to do a joint press release. I like (b) (5) [redacted].

I have some comments that you and your co-authors can take or leave:

Carlo paper:
In Methods—(b) (5) [redacted]

Page 20, "(b) (5) [redacted] The ref implies it was completed

Table 1—are there any (b) (5) [redacted]
Comment in the results/discussion about duration of (b) (5) [redacted]

For the Finer paper:
Many of the abbreviations aren't defined—would do that for each (define then use abbrev)—ie. CPAP, DR, BPD, PEEP, NRP, MAP, PDA, etc.
Would the title be more accurate to say (b) (5) [redacted]

Methods: would be helpful to clarify what (b) (5) [redacted]

First para of Intro, sentence starting "Surfactant" –need to add the word "has" before "not been

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

found"

How much (b) (5) [redacted]

How was the (b) (5) [redacted] —perhaps add to methods?
How was (b) (5) [redacted]

In results: 3rd para, (b) (5) [redacted]

Table A2–(b) (5) [redacted]

Thanks, Neil. Wally and you have done a great job with a very difficult study to address fundamental questions in neonatology. I have a few more comments to offer to further enhance the paper:

1) Abstract. Ann apparent oversight: The 2nd sentence of the Results still notes two primary outcomes (BPD by the physiologic definition and BPD by supplemental oxygen) whereas the last sentence of the introduction in the manuscript notes BPD by physiologic definition as the primary outcome and BPD by oxygen administration is later specifically noted as a secondary outcome.
2) While the method to generate the sample size is noted, the power for the primary outcome of the manuscript is not specifically noted.
We should include this (with the increase in enrollment, I would expect it would be >0.80).
3) I like what was done in Wally's paper to indicate the number of significant p values expected by chance with the multiple comparisons of secondary outcomes and subgroup analyses, and this would help to address the published NEJM requirements for subgroup analyses. In my view, you will be criticized for not emphasizing hat the subgroup difference in deaths was not pre-hypothesized. (The reason for their requirements is that except in narrowly defined circumstances, he best estimate of treatment effect in subgroups has usually been the overall treatment effect.)
4) To repeat a recommendation for Wally's paper: Provide the p value for the interaction when you present the subgroup analyses and add to the appendix a table that provides the rate of the primary outcome in each of the four treatment cells. This can be very easily done. As noted in standards for factorial designs, "accurate interpretation of factorial trials depends on the transparent reporting of data for each treatment cell' (McAlister FA, Straus SE, Sackett DL, Altman DG. Analysis and reporting of factorial trials. A systematic review JAMA 2003; 289:2545-2553.) A point often not understand by clinicians is that there can be clinically important effects of using two interventions together even in the absence of a statistical interaction. Such effects can be suggested by providing the outcomes for each cell of these tables. (See comment about using interaction ratios and calculations in Table 6 in the reference above which I would be happy to discuss if you want). After reading this you may agree that it also add such tables to the appendix for death and for BPD by the physiologic definition.
5) Ref the secondary outcome of death or BPD by supplemental oxygen: see my last (long) comment in my e mail to Wally. If the problem I noted occurred in multiple centers, this would bias the results of Wally's analyses of BPD to favor the low oxygen sat group. Though the way in which BPD was identified needs to be spelled out, this problem would not

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

bias the results of your analyses of BPD as both treatment arms had a nearly identical proportion of infants in the two oxygen saturation ranges.
6) The manuscript still contains abbreviations that NEJM has not allowed before, and the Journal explicitly discourages abbreviations in the instructions to authors.

Again, congratulations, Neil. Here's hoping both manuscripts will be accepted, and the Journal won't make your life miserable in getting to that point.

Subject: REF: Oxygen Saturation Goals

Hey, Wally, a tour de force! Congratulations and thanks for all your hard work in conducting this landmark study and preparing a concise, well written manuscript Some comments—some of which didn't occur to me before--about a few things that in my view remain to be addressed. The only comment likely to be controversial is the last one (which will be relevant to Neil's paper as well). .

1. Typos: Table 2 Pg. 26, you don't want an asterisk (limited to infants alive at 36 weeks) beside BPD (O2 use) or death at 36 weeks or beside BPD (physiologic) or death at 36 weeks. In the middle of page 20, I believe you deleted the word "birth" at the end of sentence (...oxygen restriction started soon after ...). The figure 1 that I received in your manuscript

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

(page 31) is for Neil's study. Though a relatively minor issue, it isn't clear why SE rather than SDs are shown in Table 2 (we have provided SDs using similar statistical methods in other trials, right?

2. Power is not actually specified (pg. 16). Although the number of patients enrolled was based on both outcomes and a desire to assess impairment at follow-up, you will want in this trial as for other Network trials to specify the power for the primary outcome of this study (which I anticipate will further strengthen the manuscript and its appeal to the NEJM).

3. Provide the p value for the interaction and add to the appendix a table that provides the rate of the primary outcome in each of the four treatment cells. This can be very easily done. As noted in standards for factorial designs, "accurate interpretation of factorial trials depends on the transparent reporting of data for each treatment cell' (McAlister FA, Straus SE, Sackett DL, Altman DG. Analysis and reporting of factorial trials. A systematic review JAMA 2003; 289:2545-2553.) A point often not understand by clinicians is that there can be clinically important effects of using two interventions together even in the absence of a statistical interaction. Such effects can be suggested by providing the outcomes for each cell of these tables. (See comment about using interaction ratios and calculations in Table 6 in the reference above). After reading this you may agree that it would be good with the results you happened to obtain to also add such tables to the appendix for death and for severe ROP.

4. The percent time spent within the oxygen saturation goal range for each group while receiving supplemental oxygen (is this what "present time in actually oxygen saturation range 84-96%" in the last line of Appendix Table 2 is intended to represent?) is a process measure that would be of broad interest to the readers and good to specify in the manuscript. (While the values may be lower that what we would hope for, the number represents what is currently realistic, given the instability of the infants, the nursing ratios achieved in current neonatal units, and the lack of a safe, reliable, and effective servo mechanism for adjusting FiO2 to avoid wide swings in oxygen saturation).

5. Readers may infer that neonatal units can not reduce severe ROP without increasing mortality. However, given the time outside of goal ranges, this would not necessarily be the case if we could find ways to adjust FiO2 and regulate oxygen saturation more precisely. Do you want to say anything in the Discussion about this issue?

6. You fully intended for the diagnosis of BPD by oxygen administration to be based on oxygen administration after the infant was taken off the study oximeter and his/her FIO2 was regulated as under nonstudy conditions. However, for reasons explained below, Georgia indicates that this is not what happened in Houston and perhaps multiple other centers. The study oximeter was removed at 36 weeks 1 day, and BPD by oxygen administration here represents the use of oxygen while the study oximeter was used on day 36 weeks 0 days. Of course, this would not affect the primary outcome but would produce an ascertainment bias increasing the proportion of infants in the high sat arm who had the outcomes of "death or BPD by oxygen administration" and "BPD by oxygen administration". (I think it would have little, probably trivial effect on BPD by physiologic definition which prior to study was given greater emphasis in the study protocol for reasons that Michele has documented)

The above procedure used in Houston because

* The MOP notes that the study oximeter is to be used through 36 weeks
* BPD by oxygen supplementation at 36 weeks was understood to be based on item, A6 on the NG07. The definitions for this item refer oxygen use on the day of 36 weeks postmenstrual age (e.g. as noted on page 5-3 GDB manual of operations Revised May 1, 2008). We understand this day to be the day that the infant is 36 weeks 0 days, and Georgia indicates that the audits have used 36 weeks 0 days).

In my view, we should find out what was done in other units. Perhaps Houston is the only one. In any case I see this as a minor problem that doesn't detract from the primary purpose of the study. However, we would want to acknowledge this limitation, partly because one of the BPD outcomes was significantly lower in the low sat group and because our results are likely to be added to meta-analyses from other studies. I apologize that I didn't recognize this as a problem before or during the study.

Again, Wally, congratulations on a wonderful study and thanks for all the work you have done! You have advanced the field.

The study oximeter was removed at 36 weeks 1 day, and BPD by oxygen administration here represents the use of oxygen while the study oximeter was used on day 36 weeks 0 days. Of course, this would not affect the primary outcome but would produce an ascertainment bias increasing the proportion of infants in the high sat arm who had the outcomes of "death or BPD by oxygen administration" and "BPD by oxygen administration". (I think it would have little, probably trivial effect on BPD by physiologic definition which prior to study was given greater emphasis in the study protocol for reasons that Michele has documented)

   The above procedure used in Houston because

   1. The MOP notes that the study oximeter is to be used through 36 weeks
   2. BPD by oxygen supplementation at 36 weeks was understood to be based on item, A6 on the NG07. The definitions for this item refer oxygen use on the day of 36 weeks postmenstrual age (e.g. as noted on page 5-3 GDB manual of operations Revised May 1, 2008). We understand this day to be the day that the infant is 36 weeks 0 days, and Georgia indicates that the audits have used 36 weeks 0 days).

   In my view, we should find out what was done in other units. Perhaps Houston is the only one. In any case I see this as a minor problem that doesn't detract from the primary purpose of the study. However, we would want to acknowledge this limitation, partly because one of the BPD outcomes was significantly lower in the low sat group and because our results are likely to be added to meta-analyses from other studies. I apologize that I didn't recognize this as a problem before or during the study.

Again, Wally, congratulations on a wonderful study and thanks for all the work you have done! You have advanced the field.

Subject: Confidential SUPPORT papers for submission to NEJM

Hi
Attached are the two SUPPORT papers for submission to NEJM. They will be submitted later this week.

Thanks to everyone for the **quick work in writing the papers** and the **patience and endurance** to conduct this important trial!!!

Rose

Rosemary D. Higgins, MD

As I understand, the style we are using is to put on the boiler plate
only those who are not authors.

Our boilerplate has Ambal on it - it does not have YOU from Alabama nor
me
from UCSD.
Do we need to add you to the BOILER PLATE for Alabama?? I am fine as is.
Neil

From: Hewitt, Tyl (NIH/NICHD) [E]
To: Higgins, Rosemary (NIH/NICHD) [E]
Subject: It"s me again -- Oxygen saturation paper.
Date: Tuesday, December 01, 2009 3:41:15 PM

Rose – Sorry for bothering you again but something is not very clear to me in this paper with regard to figure 2. In the text (b) (5) [redacted]

Aren't these two statements looking (b) (5) [redacted] Perhaps what is written on page 19 needs to be expanded/clarified.

We can talk about this one when you get back.

Tyl

From: Archer, Stephanie (NIH/NICHD) [E]
To: Wally Carlo, M.D.; Higgins, Rosemary (NIH/NICHD) [E]; mgantz@rti.org; adas@rti.org; nfiner@ucsd.edu
Subject: RE: The SUPPORT Trial: Randomized Trial of Oxygen Saturation Targets in Extremely Premature Infants
Date: Tuesday, December 01, 2009 1:31:50 PM
Attachments: Carlo, SUPPORT Oxygen Saturation, 2009-12-01 swa.doc

Attached is a revised version with Ambal as an author (I took him out of the boilerplate). I also deleted the table of email addresses -- that shouldn't be included in the paper, but you will likely need the addresses as part of the submission process.

From: Wally Carlo, M.D. [WCarlo@peds.uab.edu]
Sent: Tuesday, December 01, 2009 10:27 AM

Subject: The SUPPORT Trial: Randomized Trial of Oxygen Saturation Targets in Extremely Premature Infants

Dear Authors:
Dr. Carlo asked that I send draft #8 to you for your review. Your changes from over the holiday weekend have been made to this draft.

Also, Stephanie and Marie:
I included the broiler plate on this draft (#8) that we received on 11/26/09. I had a few questions about this. 1) Should Namasivayam Ambalavanan be included as an author? and 2) Should we follow the NEJM style for the broilerplate (double space, font, etc.)? Thanks very much.

Marsha

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-present).

Alpert Medical School of Brown University and Women & Infants Hospital of Rhode Island (U10 HD27904) – William Oh, MD; Angelita M. Hensman, RN BSN; Dan Gingras, RRT; Kim Francis, RN; Dawn Andrews, RN; Kristen Angela, RN.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Case Western Reserve University Rainbow Babies & Children's Hospital (U10 HD21364, GCRC M01 RR80) – Avroy A. Fanaroff, MD; Bonnie S. Siner, RN.

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants when exposed to reduced oxygenation levels. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the *Eunice Kennedy Shriver* NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85-89% or 91-95%. The primary outcome was a composite of severe retinopathy of prematurity (threshold, retinopathy, surgical ophthalmologic intervention, or bevacizumab) and/or death before discharge from the hospital.

Results

The rate of severe retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28.3 vs 32.1%; RR 0.90; CI 0.76, 1.06; p= 0.210). Death occurred more frequently in the lower oxygen saturation target group (19.9 vs 16.2%; RR 1.27; CI 1.01, 1.60; p= 0.04) while severe retinopathy among survivors occurred less often in these infants (8.6 vs 17.9%; RR 0.52; CI 0.37, 0.73; p<0.001).

Conclusions

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcome of severe retinopathy or ~~/~~death but resulted in an increase in mortality ~~that~~ and a substantial decrease in severe retinopathy among survivors. The increase in mortality is a major concern as lower saturation targeting is increasingly being advocated to prevent retinopathy of prematurity (clinicaltrials.gov NCT 00233324).

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] This resulted in the practice of restricting oxygen supplementation, which was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6,7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy,[12] and other morbidities. Although a multicenter observational study[13] could not identify an association between PaO_2 levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels ≥ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations between lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[1-3,3-5,4,5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery among very low birth weight infants was higher in infants cared for in neonatal intensive care units that used higher maximum oxygen saturation targets of ≥ 92% (3.3 ± 0.3%) or ≥98% (5.6 ± 1.1%) than in units with lower oxygen saturation targets (1.4 ± 0.2% and 3.1 ± 0.3%, respectively).[35] In a retrospective study comparing outcomes at five neonatal intensive care units, the incidence of severe retinopathy requiring

ablation therapy was 27% in units where target saturations were 88-98% and only 6% in units where the target was 70-90%.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83-95% resulted in a substantial reduction in retinopathy but actual oxygen saturations achieved, mortality, and neurodevelopmental outcomes were not reported.[4,15,16] While data from these ~~recent prospective observational studies, retrospective studies, or controlled~~ studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease ~~the incidence of~~ retinopathy of prematurity, concerns remain about the safety of these oxygen saturation targets~~an increase in serious adverse effects or deaths were not reported~~.

We conducted a 2 x 2 factorial design multicenter randomized controlled trial of two levels of oxygen saturation targeting and two ventilation approaches (continuous positive airway pressure initiated in the delivery room versus intubation with surfactant using two different protocol-driven pre-defined ventilatory strategies). The oxygen saturation component of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of the composite outcome of severe retinopathy of prematurity or death among infants of $24^{0/7}$ to $27^{6/7}$ weeks gestational age at birth. The ventilation part of this factorial design trial, which was used to control the ventilatory approach and test other hypotheses, will be reported separately.

METHODS

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The institutional review boards at all Neonatal Research Network clinical centers and at RTI, International~~Research Triangle International~~, the independent data coordinating center, approved the trial. Written informed consent was obtained from the parent or guardian of each participant before delivery.

Patients

Infants $24^{0/7}$ to $27^{6/7}$ weeks gestation for which a decision had been made to provide full resuscitation were eligible for enrollment at birth. Outborn infants and those known to have major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of sealed opaque envelopes to oxygen saturation targeting of 85-89% or 91-95% (the lower and higher oxygen saturation target groups, respectively) before birth using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88-92% for the targeted oxygen saturation ranges, with an offset of 3% (Masimo Radical Pulse Oximeter, Irvine, CA). ~~A similar algorithm was used to~~ A previous trial used a fixed 3% absolute oxygen saturation offset throughout the entire range of saturations to mask caregivers and separate oxygen saturations in premature infants.[17] The algorithm used in the current trial differed markedly as the oxygen saturation display transitioned and reverted to actual (non-skewed) values when less than 84% or

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

higher than 96% in both treatment groups. ~~Thus, a~~An oxygen saturation display of 88% corresponded to actual oxygen saturations of 85% and 91% in the 85-89% and 91-95% target groups, respectively. Likewise, an oxygen saturation display value of 92% corresponded to actual oxygen saturations of 89% and 95% in the 85-89% and 91-95% target groups, respectively. A display value of 96% corresponded to actual values of 93-96% and 96% in the low and high target groups, respectively. A display value of 84% corresponded~~s~~ to actual values of 8~~4~~7 and 84-87% in the low and high target groups, respectively. ~~The oxygen saturation display transitioned and reverted to actual (non-skewed) values when less than 84% or higher than 96% in both treatment groups.~~ Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours, whichever occurred first. Infants who weaned to room air, but who subsequently received oxygen supplementation before 36 weeks post-menstrual age, were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinical, not the research staff. Reports of displayed data by clinical center were provided quarterly to each center for feedback on displayed achieved oxygen targeting compliance~~performance~~. For the ventilation part of this 2 x 2 factorial design trial, participants were randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilatory strategy.

Assessments

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Research nurses recorded all data using standardized definitions included in the trial's Manual of Operations. Data collection, excluding retinopathy of prematurity examinations, was completed at discharge. All surviving infants were followed by ophthalmologists~~ical~~ trained in the diagnosis of ~~specialists familiar with~~ retinopathy of prematurity. Examinations began by 33 weeks postmenstrual age and continued until the study endpoint or resolution was reached. Threshold retinopathy of prematurity (New Type 1 threshold per Early Treatment of Retinopathy Cooperative Group[18,19]) was coded if any of the following findings were present:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic intervention was coded if any of the following occurred~~were present~~: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, and vitrectomy. Resolution was defined as fully vascularized retinas or immature vessels in zone III for two consecutive examinations in each eye. The primary outcome was death before discharge and/or severe retinopathy defined as threshold retinopathy and/or surgical ophthalmologic surgery and/or bevacizumab treatment for retinopathy. Other outcomes recorded included only predefined clinical diagnoses, including assessment of oxygen need at 36 weeks postmenstrual age[20] and safety outcomes.

Statistical analysis

The analysis for the oxygen saturation part of this factorial trial compared the percent of infants in each treatment arm who developed the primary outcome of severe retinopathy or death.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks and 95% confidence intervals. Continuous outcomes were analyzed using mixed effects linear models to produce adjusted means and standard errors. Survival analysis using Cox regression compared mortality in the low and high oxygen saturation groups. In the analysis of all outcomes, adjustment was performed as pre-specified for stratification by center and gestational age as well as for familial clustering due to randomization of multiple births to the same treatment arm. To compare the actual oxygen saturation values in the two treatment arms, a median oxygen saturation value while on oxygen supplementation was determined for each infant. Those values were graphed by treatment group and the medians of the resulting distributions were compared using a Rank Sums test.

An absolute difference of 10% for the composite primary outcome between the two treatment groups was considered clinically important. The sample size calculations were based on the rate of death or threshold retinopathy of 50% in the Neonatal Research Network from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or BPD in the ventilation arm of this factorial trial). Based on an intracluster correlation of 0.12 in this outcome, the sample size was increased by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because this introduced a clustering effect into the design. The required sample size was increased by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to detect, with sufficient power, an interaction effect between the two factorial arms.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Intent-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. To account for multiple testing due to the co-primary outcomes in this factorial trial, a two-sided adjusted p value of less than 0.02 was considered to be statistically significant for the primary outcome of death or severe retinopathy. P values for secondary outcomes are reported descriptively at the per-test level. Analyses of secondary outcomes did not include adjustment for multiple comparisons; however, for the ~~46~~ planned secondary outcome comparisons by treatment, we would expect no more than three tests to have a p value of less than 0.05 on the basis of chance alone. Sub-group analyses were conducted within pre-specified gestational age strata on ~~36~~ pre-defined outcomes. Although these tests were not adjusted for multiple comparisons, we would expect no more than two tests per stratum to have p values of less than 0.05 based on chance alone.

An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at approximately 25%, 50%, and 75% of planned enrollment. In addition, the Data Safety and Monitoring Committee, upon request of the investigators, evaluated the oxygen saturation data to evaluate compliance with the protocol. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of these events.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

RESULTS

1316 infants were enrolled between February 2005 and February 2009 (Figure 1). When 247 infants had been enrolled, enrollment was temporarily paused upon recommendation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and Human Development Director because of concerns that displayed oxygen saturations often exceeded the targets Separation of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns because infants not requiring supplemental oxygen accounted for a large proportion of the high saturation levels maintained. Continued enrollment was approved.

The baseline characteristics of the two treatment groups were similar (Table 1). The primary outcome, severe retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28.3 vs 32.1%; RR 0.90; CI 0.76, 1.06; p= 0.210; Table 2). Death before discharge occurred in 130 of the 654 (19.9%) infants in the lower oxygen saturation group versus in 107 of the 662 (16.2%) infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; p= 0.04; number needed to harm 27). The distribution of the major causes of death did not differ significantly between the intervention and control groups (Appendix Table 1). Comparable results were observed for both gestational age strata. Survival analysis using Cox regression produced similar results (hazard ratio 1.32; CI 1.01, 1.72; p= 0.045) (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Severe retinopathy among survivors to discharge, transfer, or one

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

year was decreased in the lower oxygen saturation group (8.6 vs 17.9%; RR 0.52; CI 0.37, 0.73; p< 0.001; number needed to treat 11). Oxygen use at 36 weeks was decreased in the lower oxygen saturation group (p=0.002) but bronchopulmonary dysplasia among survivors determined by the physiological oxygen saturation test at 36 weeks and the composite outcome of bronchopulmonary dysplasia/death by 36 weeks did not differ significantly between the treatment groups. Other pre-specified major outcomes did not differ significantly between the two treatment groups (Table 2). While the trial was not powered to detect an interaction between the oxygen saturation and the ventilatory intervention, we prospectively agreed to evaluate such interactions and none were found.

The median oxygen saturation of infants in the two treatment groups while receiving oxygen supplementation differed substantially but, as expected, there was considerable~~substantial~~ overlap (Figure 3). These data indicated that actual median oxygen saturation levels were slightly higher than targeted in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Appendix Table 2). Other measures of resource utilization did not differ as well.

DISCUSSION

In this multicenter randomized trial we found that even though lower oxygen saturation targeting reduced severe retinopathy among survivors, it also increased the risk for in-hospital mortality. Longer follow-up will be important to determine the effects on functional visual outcome.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Despite the absence of recent randomized trials and safety data and the increase in mortality when a restrictive oxygen supplementation was tested and practiced in the 1950s and 1960s, lower oxygen saturation targeting with the goal of reducing retinopathy of prematurity is becoming common practice.[3-5,15,16,21]

This is the largest randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results, in conjunction with previous reports, add to the concern that oxygen restriction may increase mortality in preterm infants. It is interesting and worrisome that the combined risk difference observed in the trials from the 1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.7% mortality increase in the lower oxygen saturation group that was observed in the current trial.

Randomized trials of oxygen restriction in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17,22] However, these trials aimed for saturations of 91-94% and 89-94% in the lower oxygen saturation group, which are closer to the targets of the higher saturation arm in the current trial. The increase in mortality in the current trial may be related either to the lower oxygen saturation targets or the use of oxygen restriction started soon after birth.~~from birth in the current trial may be related to the adverse outcome.~~

Meta-analyses of restriction of oxygen supplementation based on trials from the 1950s to the 1970s showed a large reduction in severe retinopathy (RR 0.19; CI 0.07, 0.50).[6,23] There have not been other randomized controlled trials of different oxygen targeting begun ~~starting~~ soon

Field Code Changed

after birth. However, like most non-randomized studies[3-5,15,16], our trial confirmed that lower oxygen saturation targeting results in a large reduction of severe retinopathy among survivors.

There are several ongoing trials across the world that address the same intervention tested in the current trial and a planned prospective meta-analysis.[24] These trials use the same algorithm for oxygen saturation targeting so their data will be combined in a meta-analysis to determine short and long term effects of oxygen saturation targeting.

In summary, oxygen saturation targeting in the 85-89% range did not affect the combined outcome of severe retinopathy/death but it increased mortality while substantially decreasing severe retinopathy among survivors. Neurodevelopmental assessments are being performed at 18-22 months corrected age. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years, but at the present time, caution should be exercised regarding oxygen targeting for premature infants in the low range tested as it may lead to increased mortality.

Table 1. Baseline Characteristics of the Patients in a Randomized Trial of Lower versus Higher Oxygen Saturation Targets in Extremely Low Birth Weight Infants

Characteristic	Lower Saturation Group (N = 654)	Higher Saturation Group (N = 662)
Birthweight – g (m±SD)	836±193	825±193
Gestational age – wk (m±SD)	26±1	26±1
Male sex – no. (%)	341/654 (52.1)	371/662 (56.0)
Race or ethnic group – no. (%)		
White (non-Hispanic)	242/654 (37.0)	279/662 (42.1)
Black (non-Hispanic)	257/654 (39.3)	232/662 (35.0)
Hispanic	132/654 (20.2)	127/662 (19.2)
Other/unknown	23/654 (3.5)	24/662 (3.6)
Antenatal corticosteroids (any) – no. (%)	633/654 (96.8)	632/661 (95.6)
Antenatal corticosteroids (full course) – no. (%)	477/651 (73.3)	462/658 (70.2)
5-min Apgar score < 3 – no. (%)	34/654 (5.2)	24/662 (3.6)
Surfactant – no. (%)	531/653 (81.32)	558/660 (84.5)

Table 2. Major Outcomes in a Randomized Trial of Lower versus Higher Oxygen Saturation Targets in Extremely Low Birth Weight Infants

Outcome – no./total no. (%)	Lower Saturation Group N=654 n/N (%)	Higher Saturation Group N=662 n/N (%)	Adjusted Relative Risk[†] (95% CI)
Severe retinopathy/death	170/605 (28.1)	198/616 (32.1)	0.90 (0.76, 1.06)
Severe retinopathy	41/475 (8.6)	91/509 (17.9)	0.52 (0.37, 0.73)
Death before discharge	130/654 (19.9)	107/662 (16.2)	1.27 (1.01, 1.60)
Death by 7 days	41/654 (6.3)	38/662 (5.7)	1.11 (0.72, 1.72)
Death by 14 days	64/654 (9.8)	56/662 (8.5)	1.20 (0.84, 1.70)
Death by 36 weeks post-menstrual age	114/654 (17.4)	94/662 (14.2)	1.27 (0.99, 1.63)
Bronchopulmonary dysplasia by O_2 use at 36 weeks*	203/540 (37.6)	265/568 (46.7)	0.82 (0.72, 0.93)
Bronchopulmonary dysplasia (O_2 use) or death by 36 weeks*	317/654 (48.5)	359/662 (54.2)	0.91 (0.83, 1.01)
Bronchopulmonary dysplasia (physiologic) at 36 weeks*	205/540 (38.0)	237/568 (41.7)	0.92 (0.81, 1.05)
Bronchopulmonary dysplasia (physiologic) or death by 36 weeks*	319/654 (48.8)	331/662 (50.0)	0.99 (0.90, 1.10)
Intraventricular hemorrhage, grade 3 or 4	83/630 (13.2)	81/640 (12.7)	1.06 (0.80, 1.40)
Intraventricular hemorrhage, grade 3 or 4 or death	179/653 (27.4)	156/661 (23.6)	1.18 (0.99, 1.42)
Cystic periventricular leukomalacia	24/631 (3.8)	30/641 (4.7)	0.83 (0.49, 1.42)
Cystic periventricular leukomalacia or death	149/654 (22.8)	132/662 (19.9)	1.18 (0.96, 1.45)
Necrotizing enterocolitis, stage ≥ 2	76/641 (11.9)	70/649 (10.8)	1.11 (0.82, 1.51)
Necrotizing enterocolitis, stage ≥ 2 or death	176/654 (26.9)	155/662 (23.4)	1.18 (0.98, 1.43)
Late onset sepsis	228/624 (36.5)	226/634 (35.6)	1.03 (0.89, 1.18)
Late onset sepsis or death	300/654 (45.9)	291/662 (44.0)	1.05 (0.94, 1.18)
Patent ductus arteriosus	307/641 (47.9)	324/648 (50.0)	0.96 (0.86, 1.07)
Medical treatment for patent ductus arteriosus	219/634 (34.5)	233/645 (36.1)	0.95 (0.82, 1.09)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Surgical treatment for patent ductus arteriosus	73/641 (11.4)	68/648 (10.5)	1.09 (0.80, 1.48)
Pneumothorax – no. (%)	47/654 (7.1)	43/662 (6.5)	1.12 (0.74, 1.68)
Any air leaks in the first 14 days – no. (%)	51/654 (7.8)	42/662 (6.5)	1.23 (0.83, 1.83)
Postnatal steroids for bronchopulmonary dysplasia	61/636 (9.6)	69/644 (10.7)	0.91 (0.67, 1.24)

*In babies alive at 36 weeks post-menstrual age.

†Adjusted for stratification factors (study center and GA group) as well as for familial clustering

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Appendix Table 1: Cause of Death in a Randomized Trial of Lower versus Higher Oxygen Saturation Targets in Extremely Low Birth Weight Infants

Category – no./total no. (%)	Lower Saturation Group n/N (%)	Higher Saturation Group n/N (%)
Respiratory distress syndrome	31/130 (23.8)	31/107 (29.0)
Infection	25/130 (19.2)	21/107 (19.6)
Necrotizing enterocolitis	23/130 (17.7)	14/107 (13.1)
Bronchopulmonary dysplasia	14/130 (10.8)	10/107 (9.3)
Central nervous system insult	12/130 (9.2)	9/107 (8.4)
Immaturity	7/130 (5.4)	3/107 (2.8)
Other	18/130 (13.8)	19/107 (17.8)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Appendix Table 2. Other Outcomes in a Randomized Trial of Lower versus Higher Oxygen Saturation Targets in Extremely Low Birth Weight Infants

Outcome	Lower Saturation Group	Higher Saturation Group	Adjusted P value[§]
Length of stay any hospital, (days) m±SE*	104.5 ± 2.0	106.4 ± 2.0	0.45
Length of stay at study hospital, (days) m±SE*	99.8 ± 2.0	103.0 ± 2.0	0.22
Duration of mechanical ventilation, (days) m±SE[†]	25.5 ± 1.1	26.9 ± 1.0	0.30
Duration of oxygen supplementation, (days) m±SE[†]	59.8 ± 1.6	67.4 ± 1.5	<0.001
Continuous positive airway pressure, (days) m±SE[†]	17.1 ± 0.6	17.0 ± 0.6	0.94
Nasal synchronized intermittent mandatory ventilation, (days) m±SE[†]	3.3 ± 0.3	3.8 ± 0.3	0.14
Alive off mechanical ventilation by day 14, (days) – no. (%)	332/644 (51.6)	326/655 (49.8)	0.86
Alive off mechanical ventilation by day 7, (days) – no. (%)	351/648 (54.2)	329/659 (49.9)	0.27
Precent of time in actual oxygen saturation range 84-96%, (%) m±SD‡	66.9 ± 13.9	68.0 ± 15.2	0.16¶

*Among survivors to discharge, transfer or one year; maximum value is 366 days

[†]Among survivors to discharge, transfer or 120 days; maximum value is 120 days

‡Percent of time based only on total time on oxygen supplementation

§Adjusted for stratification factors (study center, gestational age group) as well as for familial clustering

¶Unadjusted P value

Legends

Figure 1. Flow chart of the screening, random assignment, and primary outcome. ROP denotes severe retinopathy of prematurity. The numbers excludes pregnancies screened which did not subsequently result in a birth at a study center at $24^{0/7}$ to $27^{6/7}$ weeks. The question marks in the ROP outcome boxes are for infants in whom the final ROP outcome could not be ascertained because of loss to follow up.

Figure 2. ~~Survival curve~~Survivor curve for mortality. Cox regression analysis indicated that there was a significantly higher hazard of death in the lower oxygen saturation group (hazard ratio 1.32; CI 1.01, 1.72; p= 0.045).

Figure 3. Median actual oxygen saturations while on oxygen supplementation for infants in each of the treatment groups. ~~The median oxygen saturations were significantly lower for infants in the 85 to 89% oxygen saturation target group.~~ The medians of the distributions were significantly different based on a Rank Sums test ($p < 0.001$).

Ambal should be on both papers; no one reported any conflicts (and we had everyone).

Let me know if you need anything else

Rose

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-present).

Alpert Medical School of Brown University and Women & Infants Hospital of Rhode Island (U10 HD27904) – William Oh, MD; Angelita M. Hensman, RN BSN; Dan Gingras, RRT; Kim Francis, RN; Dawn Andrews, RN; Kristen Angela, RN.

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants when exposed to reduced oxygenation levels. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the *Eunice Kennedy Shriver* NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85-89% or 91-95%. The primary outcome was a composite of severe retinopathy of prematurity (threshold, retinopathy, surgical ophthalmologic intervention, or bevacizumab) and/or death before discharge from the hospital.

Results

The rate of severe retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28.3 vs 32.1%; RR 0.90; CI 0.76, 1.06; p= 0.21). Death occurred more frequently in the lower oxygen saturation target group (19.9 vs 16.2%; RR 1.27; CI 1.01, 1.60; p= 0.04) while severe retinopathy among survivors occurred less often in these infants (8.6 vs 17.9%; RR 0.52; CI 0.37, 0.73; p<0.001).

Conclusions

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcome of severe retinopathy or death but resulted in an increase in mortality and a substantial decrease in severe retinopathy among survivors. The increase in mortality is a major concern as lower saturation targeting is increasingly being advocated to prevent retinopathy of prematurity (clinicaltrials.gov NCT 00233324).

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] This resulted in the practice of restricting oxygen supplementation, which was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6,7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy,[12] and other morbidities. Although a multicenter observational study[13] could not identify an association between PaO_2 levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations between lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3-5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery among very low birth weight infants was higher in infants cared for in neonatal intensive care units that used higher maximum oxygen saturation targets of $\geq$ 92% (3.3 $\pm$ 0.3%) or $\geq$98% (5.6 $\pm$ 1.1%) than in units with lower oxygen saturation targets (1.4 $\pm$ 0.2% and 3.1 $\pm$ 0.3%, respectively).[5] In a retrospective study comparing outcomes at five neonatal intensive care units, the incidence of severe retinopathy requiring ablation therapy was

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

27% in units where target saturations were 88-98% and only 6% in units where the target was 70-90%.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83-95% resulted in a substantial reduction in retinopathy but actual oxygen saturations achieved, mortality, and neurodevelopmental outcomes were not reported.[4,15,16] While data from these studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease retinopathy of prematurity, concerns remain about the safety of these oxygen saturation targets.

We conducted a 2 x 2 factorial design multicenter randomized controlled trial of two levels of oxygen saturation targeting and two ventilation approaches (continuous positive airway pressure initiated in the delivery room versus intubation with surfactant using two different protocol-driven pre-defined ventilatory strategies). The oxygen saturation component of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of the composite outcome of severe retinopathy of prematurity or death among infants of $24^{0/7}$ to $27^{6/7}$ weeks gestational age at birth. The ventilation part of this factorial design trial, which was used to control the ventilatory approach and test other hypotheses, will be reported separately.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at Research Triangle International, the independent data coordinating center, approved the trial.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Written informed consent was obtained from the parent or guardian of each participant before delivery.

Patients

Infants $24^{0/7}$ to $27^{6/7}$ weeks gestation for which a decision had been made to provide full resuscitation were eligible for enrollment at birth. Outborn infants and those known to have major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of sealed opaque envelopes to oxygen saturation targeting of 85-89% or 91-95% (the lower and higher oxygen saturation target groups, respectively) before birth using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88-92% for the targeted oxygen saturation ranges, with an offset of 3% (Masimo Radical Pulse Oximeter, Irvine, CA). A previous trial used a fixed 3% absolute oxygen saturation offset throughout the entire range of saturations to mask caregivers and separate oxygen saturations in premature infants.[17] The algorithm used in the current trial differed markedly as the oxygen saturation display transitioned and reverted to actual (non-skewed) values when less than 84% or higher than 96% in both treatment groups. An oxygen saturation display of 88% corresponded to actual oxygen saturations of 85% and 91% in the 85-89% and 91-95% target groups, respectively. Likewise, an

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

oxygen saturation display value of 92% corresponded to actual oxygen saturations of 89% and 95% in the 85-89% and 91-95% target groups, respectively. A display value of 96% corresponded to actual values of 93-96% and 96% in the low and high target groups, respectively. A display value of 84% corresponded to actual values of 84 and 84-87% in the low and high target groups, respectively. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours, whichever occurred first. Infants who weaned to room air, but who subsequently received oxygen supplementation before 36 weeks post-menstrual age, were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinical, not the research staff. Reports of displayed data by clinical center were provided quarterly to each center for feedback on displayed achieved oxygen targeting compliance. For the ventilation part of this 2 x 2 factorial design trial, participants were randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilatory strategy.

Assessments

Research nurses recorded all data using standardized definitions included in the trial's Manual of Operations. Data collection, excluding retinopathy of prematurity examinations, was completed at discharge. All surviving infants were followed by ophthalmologists trained in the diagnosis of retinopathy of prematurity. Examinations began by 33 weeks postmenstrual age and continued until the study endpoint or resolution was reached. Threshold retinopathy of prematurity (New

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Type 1 threshold per Early Treatment of Retinopathy Cooperative Group[18,19]) was coded if any of the following findings were present:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic intervention was coded if any of the following occurred: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, and vitrectomy. Resolution was defined as fully vascularized retinas or immature vessels in zone III for two consecutive examinations in each eye. The primary outcome was death before discharge and/or severe retinopathy defined as threshold retinopathy and/or surgical ophthalmologic surgery and/or bevacizumab treatment for retinopathy. Other outcomes recorded included only predefined clinical diagnoses, including assessment of oxygen need at 36 weeks postmenstrual age[20] and safety outcomes.

Statistical analysis

The analysis for the oxygen saturation part of this factorial trial compared the percent of infants in each treatment arm who developed the primary outcome of severe retinopathy or death. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks and 95% confidence intervals. Continuous outcomes were analyzed using mixed effects linear models to produce adjusted means and standard errors. Survival analysis using Cox regression compared mortality in the low and high oxygen saturation groups. In the analysis of all outcomes, adjustment was performed as pre-specified for stratification by center and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

gestational age as well as for familial clustering due to randomization of multiple births to the same treatment arm. To compare the actual oxygen saturation values in the two treatment arms, a median oxygen saturation value while on oxygen supplementation was determined for each infant. Those values were graphed by treatment group and the medians of the resulting distributions were compared using a Rank Sums test.

An absolute difference of 10% for the composite primary outcome between the two treatment groups was considered clinically important. The sample size calculations were based on the rate of death or threshold retinopathy of 50% in the Neonatal Research Network from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or BPD in the ventilation arm of this factorial trial). Based on an intracluster correlation of 0.12 in this outcome, the sample size was increased by a factor of 1.12 to allow for multiples to be randomized to the same treatment because this introduced a clustering effect into the design. The required sample size was increased by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to detect, with sufficient power, an interaction effect between the two factorial arms.

Intent-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. To account for multiple testing due to the co-primary outcomes in this factorial trial, a two-sided adjusted p value of less than 0.02 was considered to be statistically significant for the primary outcome of death or severe retinopathy. P values for secondary

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

outcomes are reported descriptively at the per-test level. Analyses of secondary outcomes did not include adjustment for multiple comparisons; however, for the planned secondary outcome comparisons by treatment, we would expect no more than three tests to have a p value of less than 0.05 on the basis of chance alone. Sub-group analyses were conducted within pre-specified gestational age strata on 36 pre-defined outcomes. Although these tests were not adjusted for multiple comparisons, we would expect no more than two tests per stratum to have p values of less than 0.05 based on chance alone.

An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at approximately 25%, 50%, and 75% of planned enrollment. In addition, the Data Safety and Monitoring Committee, upon request of the investigators, evaluated the oxygen saturation data to evaluate compliance with the protocol. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of these events.

RESULTS

1316 infants were enrolled between February 2005 and February 2009 (Figure 1). When 247 infants had been enrolled, enrollment was temporarily paused upon recommendation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Human Development Director because of concerns that displayed oxygen saturations often exceeded the targets Separation of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns because infants not requiring supplemental oxygen accounted for a large proportion of the high saturation levels maintained. Continued enrollment was approved.

The baseline characteristics of the two treatment groups were similar (Table 1). The primary outcome, severe retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28.3 vs 32.1%; RR 0.90; CI 0.76, 1.06; p= 0.21; Table 2). Death before discharge occurred in 130 of the 654 (19.9%) infants in the lower oxygen saturation group versus in 107 of the 662 (16.2%) infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; p= 0.04; number needed to harm 27). The distribution of the major causes of death did not differ significantly between the intervention and control groups (Appendix Table 1). Comparable results were observed for both gestational age strata. Survival analysis using Cox regression produced similar results (hazard ratio 1.32; CI 1.01, 1.72; p= 0.045) (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Severe retinopathy among survivors to discharge, transfer, or one year was decreased in the lower oxygen saturation group (8.6 vs 17.9%; RR 0.52; CI 0.37, 0.73; p< 0.001; number needed to treat 11). Oxygen use at 36 weeks was decreased in the lower oxygen saturation group (p=0.002) but bronchopulmonary dysplasia among survivors determined by the physiological oxygen saturation test at 36 weeks and the composite outcome of bronchopulmonary dysplasia/death by 36 weeks did not differ significantly between the treatment groups. Other pre-specified major outcomes did not differ significantly between the

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

two treatment groups (Table 2). While the trial was not powered to detect an interaction between the oxygen saturation and the ventilatory intervention, we prospectively agreed to evaluate such interactions and none were found.

The median oxygen saturation of infants in the two treatment groups while receiving oxygen supplementation differed substantially but, as expected, there was considerable overlap (Figure 3). These data indicate that actual median oxygen saturation levels were slightly higher than targeted in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Appendix Table 2). Other measures of resource utilization did not differ as well.

DISCUSSION

In this multicenter randomized trial we found that even though lower oxygen saturation targeting reduced severe retinopathy among survivors, it also increased the risk for in-hospital mortality. Longer follow-up will be important to determine the effects on functional visual outcome. Despite the absence of recent randomized trials and safety data and the increase in mortality when a restrictive oxygen supplementation was tested and practiced in the 1950s and 1960s, lower oxygen saturation targeting with the goal of reducing retinopathy of prematurity is becoming common practice.[3-5,15,16,21]

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

This is the largest randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results, in conjunction with previous reports, add to the concern that oxygen restriction may increase mortality in preterm infants. It is interesting and worrisome that the combined risk difference observed in the trials from the 1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.7% mortality increase in the lower oxygen saturation group that was observed in the current trial.

Randomized trials of oxygen restriction in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17,22] However, these trials aimed for saturations of 91-94% and 89-94% in the lower oxygen saturation group, which are closer to the targets of the higher saturation arm in the current trial. The increase in mortality in the current trial may be related either to the lower oxygen saturation targets or the use of oxygen restriction started soon after.

Meta-analyses of restriction of oxygen supplementation based on trials from the 1950s to the 1970s showed a large reduction in severe retinopathy (RR 0.19; CI 0.07, 0.50).[1,23] There have not been other randomized controlled trials of different oxygen targeting begun soon after birth. However, like most non-randomized studies[3-5,15,16], our trial confirmed that lower oxygen saturation targeting results in a large reduction of severe retinopathy among survivors.

There are several ongoing trials across the world that address the same intervention tested in the current trial and a planned prospective meta-analysis.[24] These trials use the same algorithm for

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

oxygen saturation targeting so their data will be combined in a meta-analysis to determine short and long term effects of oxygen saturation targeting.

In summary, oxygen saturation targeting in the 85-89% range did not affect the combined outcome of severe retinopathy/death but it increased mortality while substantially decreasing severe retinopathy among survivors. Neurodevelopmental assessments are being performed at 18-22 months corrected age. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years, but at the present time, caution should be exercised regarding oxygen targeting for premature infants in the low range tested as it may lead to increased mortality.

Table 1. Baseline Characteristics of the Patients in a Randomized Trial of Lower versus Higher Oxygen Saturation Targets in Extremely Low Birth Weight Infants

Characteristic	Lower Saturation Group (N = 654)	Higher Saturation Group (N = 662)
Birthweight – g (m±SD)	836±193	825±193
Gestational age – wk (m±SD)	26±1	26±1
Male sex – no. (%)	341/654 (52.1)	371/662 (56.0)
Race or ethnic group – no. (%)		
White (non-Hispanic)	242/654 (37.0)	279/662 (42.1)
Black (non-Hispanic)	257/654 (39.3)	232/662 (35.0)
Hispanic	132/654 (20.2)	127/662 (19.2)
Other/unknown	23/654 (3.5)	24/662 (3.6)
Antenatal corticosteroids (any) – no. (%)	633/654 (96.8)	632/661 (95.6)
Antenatal corticosteroids (full course) – no. (%)	477/651 (73.3)	462/658 (70.2)
5-min Apgar score < 3 – no. (%)	34/654 (5.2)	24/662 (3.6)
Surfactant – no. (%)	531/653 (81.3)	558/660 (84.5)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Table 2. Major Outcomes in a Randomized Trial of Lower versus Higher Oxygen Saturation Targets in Extremely Low Birth Weight Infants

Outcome – no./total no. (%)	Lower Saturation Group N=654 n/N (%)	Higher Saturation Group N=662 n/N (%)	Adjusted Relative Risk† (95% CI)
Severe retinopathy/death	170/605 (28.1)	198/616 (32.1)	0.90 (0.76, 1.06)
Severe retinopathy	41/475 (8.6)	91/509 (17.9)	0.52 (0.37, 0.73)
Death before discharge	130/654 (19.9)	107/662 (16.2)	1.27 (1.01, 1.60)
Death by 7 days	41/654 (6.3)	38/662 (5.7)	1.11 (0.72, 1.72)
Death by 14 days	64/654 (9.8)	56/662 (8.5)	1.20 (0.84, 1.70)
Death by 36 weeks post-menstrual age	114/654 (17.4)	94/662 (14.2)	1.27 (0.99, 1.63)
Bronchopulmonary dysplasia by O_2 use at 36 weeks*	203/540 (37.6)	265/568 (46.7)	0.82 (0.72, 0.93)
Bronchopulmonary dysplasia (O_2 use) or death by 36 weeks*	317/654 (48.5)	359/662 (54.2)	0.91 (0.83, 1.01)
Bronchopulmonary dysplasia (physiologic) at 36 weeks*	205/540 (38.0)	237/568 (41.7)	0.92 (0.81, 1.05)
Bronchopulmonary dysplasia (physiologic) or death by 36 weeks*	319/654 (48.8)	331/662 (50.0)	0.99 (0.90, 1.10)
Intraventricular hemorrhage, grade 3 or 4	83/630 (13.2)	81/640 (12.7)	1.06 (0.80, 1.40)
Intraventricular hemorrhage, grade 3 or 4 or death	179/653 (27.4)	156/661 (23.6)	1.18 (0.99, 1.42)
Cystic periventricular leukomalacia	24/631 (3.8)	30/641 (4.7)	0.83 (0.49, 1.42)
Cystic periventricular leukomalacia or death	149/654 (22.8)	132/662 (19.9)	1.18 (0.96, 1.45)
Necrotizing enterocolitis, stage ≥ 2	76/641 (11.9)	70/649 (10.8)	1.11 (0.82, 1.51)
Necrotizing enterocolitis, stage ≥ 2 or death	176/654 (26.9)	155/662 (23.4)	1.18 (0.98, 1.43)
Late onset sepsis	228/624 (36.5)	226/634 (35.6)	1.03 (0.89, 1.18)
Late onset sepsis or death	300/654 (45.9)	291/662 (44.0)	1.05 (0.94, 1.18)
Patent ductus arteriosus	307/641 (47.9)	324/648 (50.0)	0.96 (0.86, 1.07)
Medical treatment for patent ductus arteriosus	219/634 (34.5)	233/645 (36.1)	0.95 (0.82, 1.09)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Surgical treatment for patent ductus arteriosus	73/641 (11.4)	68/648 (10.5)	1.09 (0.80, 1.48)
Pneumothorax – no. (%)	47/654 (7.1)	43/662 (6.5)	1.12 (0.74, 1.68)
Any air leaks in the first 14 days – no. (%)	51/654 (7.8)	42/662 (6.5)	1.23 (0.83, 1.83)
Postnatal steroids for bronchopulmonary dysplasia	61/636 (9.6)	69/644 (10.7)	0.91 (0.67, 1.24)

*In babies alive at 36 weeks post-menstrual age.

Appendix Table 1: Cause of Death in a Randomized Trial of Lower versus Higher Oxygen Saturation Targets in Extremely Low Birth Weight Infants

Category – no./total no. (%)	Lower Saturation Group n/N (%)	Higher Saturation Group n/N (%)
Respiratory distress syndrome	31/130 (23.8)	31/107 (29.0)
Infection	25/130 (19.2)	21/107 (19.6)
Necrotizing enterocolitis	23/130 (17.7)	14/107 (13.1)
Bronchopulmonary dysplasia	14/130 (10.8)	10/107 (9.3)
Central nervous system insult	12/130 (9.2)	9/107 (8.4)
Immaturity	7/130 (5.4)	3/107 (2.8)
Other	18/130 (13.8)	19/107 (17.8)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Appendix Table 2. Other Outcomes in a Randomized Trial of Lower versus Higher Oxygen Saturation Targets in Extremely Low Birth Weight Infants

Outcome	Lower Saturation Group	Higher Saturation Group	Adjusted P value‡
Length of stay any hospital, (days) m+SE*	104.5 ± 2.0	106.4 ± 2.0	0.45
Length of stay at study hospital, (days) m+SE*	99.8 ± 2.0	103.0 ± 2.0	0.22
Duration of mechanical ventilation, (days) m+SE†	25.5 ± 1.1	26.9 ± 1.0	0.30
Duration of oxygen supplementation, (days) m+SE†	59.8 ± 1.6	67.4 ± 1.5	0.0002
Continuous positive airway pressure, (days) m+SE†	17.1 ± 0.6	17.0 ± 0.6	0.94
Nasal synchronized intermittent mandatory ventilation, (days) m+SE†	3.3 ± 0.3	3.8 ± 0.3	0.14
Alive off mechanical ventilation by day 14, (days) – no. (%)	332/644 (51.6)	326/655 (49.8)	0.86
Alive off mechanical ventilation by day 7, (days) – no. (%)	351/648 (54.2)	329/659 (49.9)	0.27
Present time in actual oxygen saturation range 84-96%, %	66.9 ± 13.9	68.0 ± 13.9	0.16

*Among survivors to discharge, transfer or one year; maximum value is 366 days

†Among survivors to discharge, transfer or 120 days; maximum value is 120 days

‡Adjusted for stratification factors (study center, gestational age group) as well as for familial clustering

Legends

Figure 1. Flow chart of the screening, random assignment, and primary outcome. ROP denotes severe retinopathy of prematurity. The numbers excludes pregnancies screened which did not subsequently result in a birth at a study center at $24^{0/7}$ to $27^{6/7}$ weeks. The question marks in the ROP outcome boxes are for infants in whom the first ROP outcome could not be ascertained because of loss to follow up.

Figure 2. Survivor curve for mortality. Cox regression analysis indicated that there was a significantly higher hazard of death in the lower oxygen saturation group (hazard ratio 1.32; CI 1.01, 1.72; p= 0.045).

Figure 3. Median actual oxygen saturations while on oxygen supplementation for infants in each of the treatment groups. The medians of the distributions were significantly different based on a Rank Sums test ($p < 0.001$).

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-present).

Abstract: 244

Manuscript: 2699

Running head: Early CPAP versus Surfactant and outcomes of prematurity

Key words: CPAP, bronchopulmonary dysplasia, extremely low birth weight infant, neonatal mortality, surfactant

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths to 27 6/7ths weeks gestation. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilation strategy. Infants randomized to surfactant were to be intubated in the delivery room and received surfactant within 60 minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcomes of death or BPD, using the physiologic definition and death or BPD using the receipt of supplemental oxygen at 36 weeks were non-significantly reduced in the CPAP group compared to the surfactant group, when adjusted for gestational age, center and familial clustering (47.8% vs. 51.0%, Relative risk(RR) =0.95 (95% Confidence interval (CI) 0.85, 1.05) p=0.304, 48.7% vs. 54.1%, RR=0.91 (CI 0.82, 1.01), p=0.072). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001).

Conclusions: CPAP as used in this study is an effective evidence-based alternative to intubation and surfactant in preterm infants.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and death or BPD in

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

preterm infants.[12] Overall prophylactic surfactant has not been reported to significantly reduce BPD alone, whereas early compared with selective later surfactant has been associated with a decreased risk of chronic lung disease.[2] Surfactant not been found to significantly reduce subsequent neurodevelopmental impairment.[3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with respiratory distress documenting a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP.[4,5,6,7,8,9]

The recent trial by Morley et al randomized 610 infants from 25 0/7 to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H_20. CPAP infants were intubated if they met failure criteria.[10] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analysis[11]. There was a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006). The primary outcome of death or BPD at 36 weeks was non-significantly reduced in the CPAP arm, 33.9% vs 38.9%, (OR=0.58 to 1.12; P=0.19)

The SUPPORT trial was designed to compare early CPAP to early surfactant for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design. The results for the oximetry study will be reported

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

separately. The primary hypothesis of this trial was that in infants of 24 to 27 weeks gestation the use of early CPAP and a protocol driven strategy of limited ventilation with continuing CPAP in the NICU infants would result in an increased survival without BPD at 36 weeks using the physiologic definition compared to infants managed with surfactant within an hour of birth, and a subsequent conventional ventilator strategy.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol driven limited ventilation begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by a conventional ventilation strategy.

Infants were also randomized to a prospective comparison of a lower target SpO2 range (85% to 89%) with a higher more conventional target SpO2 range (91% to 95%) until the infant was 36 weeks or no longer received ventilatory support or oxygen.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a randomizing center, for whom a decision had been made to provide full resuscitation, and parental consent obtained. The infants were randomized within each center to two gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used for the delivery room administration of CPAP. CPAP or ventilation with PEEP, both at a recommended 5 cm H_2O, was utilized if the infant received positive pressure during resuscitation. CPAP was continued until admission to the NICU. CPAP infants were not to be intubated exclusively for surfactant administration in the DR. CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.[12]

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life, infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a $PaCO_2$ < 65 torr with a pH > 7.20, an SpO_2 > 88% with an FiO_2 < 50%, a mean airway pressure (MAP) < 10 cm H_2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations, CPAP infants were treated using NICU standard practice.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Surfactant Arm: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2 < 50$ torr and pH > 7.30, $FiO_2 \leq .35$ with a $SpO_2 \geq 88\%$, a MAP $\leq$ 8 cm H_2O, ventilator rate $\leq$ 20 bpm, an amplitude < 2X MAP if on HFV, and hemodynamically stable without evidence of clinically significant PDA. Once extubated, Surfactant infants were treated using NICU standard practice.

These criteria for both arms were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN baseline occurrence data (BPD 67%, NDI 61%). We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment because this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after discharge and before follow-up. Using a conservative 2% level of significance to account for the co-primary outcome of death or severe ROP in the SpO2 arm of this factorial

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

trial resulted in a required sample size of 1310 infants. This sample size was not powered to detect an interaction effect between the 2 factorial arms.

The Physiologic Definition of BPD assigned the diagnosis of BPD to any infant who received more than 30% oxygen at 36 weeks or who required positive pressure support, but required demonstration of oxygen dependence by an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks. [1314] Pre-specified secondary outcomes included the evaluation of BPD defined by the receipt of oxygen at 36 weeks.

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks post menstrual age (PMA) without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks with 95% confidence intervals. Continuous outcomes were analyzed using mixed effects linear models to produce adjusted means and standard errors. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering. To account for multiple testing due to the co-primary outcomes in this factorial trial, a two-sided p value of less than 0.02 was considered statistically significant for the primary outcome of death or BPD. P values for secondary outcomes are reported descriptively at the per-test level. Analyses of secondary outcomes did not include adjustment for multiple comparisons.

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

The study was approved by Human Subjects Committees at all sites and RTI, the NRN data center. Parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled from February 2005 through February 2009. There were 565 infants enrolled in the lower gestational age strata (24 0/7 to 25 6/7 wks), and 751 in the higher strata 26 0/7 to 27 6/7 wks) (Figure). There were no significant differences for sex, birth weight, or race between the 2 treatment groups (Table 1).

Data regarding delivery room interventions is provided in Table 2. Fewer CPAP infants received positive pressure ventilation or epinephrine in the delivery room compared with the surfactant infants. Intubation in the DR was significantly decreased in the CPAP infants, and 32.9% of CPAP infants never received surfactant during their hospitalization.

The post delivery room outcomes are provided in Table 3. The primary outcome of death or BPD, using either the physiologic definition or the need for supplemental oxygen at 36 weeks

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

post menstrual age did not reach statistical significance when adjusted for gestational age, center and familial clustering as pre-specified.

Death during the hospitalization was non-significantly lower for the CPAP group overall. There was no significant difference in the occurrence of BPD among survivors to 36 weeks post menstrual age using either the Physiologic Definition or the receipt of oxygen at 36 weeks (Table 3).

There were no significant differences overall for death in the delivery room, length of stay, or days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, ($p=0.011$). There were no significant differences between the groups for air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but 2 infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who were intubated during their nursery course ($p<0.001$). There was a reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (7.2% vs. 13.2%, $p<0.001$) (Table 3). The incidence of severe retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[15] or need for surgical intervention or bevacizumab treatment for ROP among survivors was not different in the CPAP compared to the surfactant infants (Table 3). While the study was not powered to detect an interaction between the two interventions, we prospectively agreed to evaluate such interactions and none were found.

Strata Results: 24 – 25 weeks Gestation

CPAP infants in this stratum had a significantly lower mortality while hospitalized 23.9% vs. 32.1%, RR=0.74, (0.57, 0.98), p=0.034 (Appendix Table A1). Causes of death for this stratum are reported in Appendix Table A2.

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups in this stratum, 10.8% vs 10.2%. (Appendix Table A3).

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP initiated in the delivery room with early surfactant in very preterm infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. In a pilot trial we found that 100% of infants of 23 weeks gestation required intubation in the delivery room, and decided that such infants would unlikely be successfully treated with CPAP alone.[16] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[17]

Our trial differs from the recently reported trial of Morley et al[10~~10~~15] in that we randomized all eligible preterm infants irrespective of whether they demonstrated spontaneous breathing and enough respiratory distress to warrant intervention. We also included infants of 24 weeks gestation and compared CPAP and a protocol driven strategy of limited ventilation with infants

who were to receive surfactant within 1 hour of birth and a conventional strategy. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that units with the most success using CPAP also utilized a higher threshold for intubation and the initiation of mechanical ventilation. [Error! Bookmark not defined.~~Error! Bookmark not defined.~~4,Error! Bookmark not defined.~~Error! Bookmark not defined.~~5,Error! Bookmark not defined.~~Error! Bookmark not defined.~~6] The infants who received surfactant were treated with a ventilation approach that was used by a majority of NRN units before the trial began. We believed that comparing these two methods would provide more clinically relevant results.

We prospectively identified safety outcomes that we chose to follow as investigators. These included: the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H_2O compared to the use of early surfactant.

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO_2 target range. The randomization resulted in a balance between the infants randomized to each intervention within the pre-specified gestational age strata (Figure, Table 1). While the study was not powered to detect an interaction between the 2 interventions, we prospectively agreed to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the primary outcomes. Data on survival without neurodevelopmental impairment at 18 to 22 months are currently accruing, and these results will be presented after all survivors have been assessed.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was not associated with any increase in death or BPD, or in any adverse neonatal outcomes. BPD using either the physiologic definition or the receipt of oxygen at 36 weeks was decreased but these differences were not statistically significant. We also noted a clinically significant 8.2% reduction in death in the CPAP infants of our 24 to 25 week stratum. While we did not postulate such a difference in the individual stratum this increased occurrence of death is cause for concern. The 565 infants in our 24 to 25 week stratum to our knowledge represent the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal steroids and a reduction in BPD or death by 36 weeks post menstrual age in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Conclusions:

Infants between 24 and 27 6/7ths weeks gestation assigned to treatment with CPAP have a non significant reduction in the incidence of death or BPD, with no demonstrable increase in any adverse neonatal outcome when compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth. Multiple secondary outcomes

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

including death in the immature stratum favored the CPAP group. CPAP as used in this study is an effective evidence-based alternative to intubation and surfactant in preterm infants.

Figure: Consort Diagram

Legend: Flow chart of the screening, random assignment, and primary outcome. Survival is to 36 weeks post menstrual age. BPD denotes bronchopulmonary dysplasia by the physiologic definition. The numbers exclude pregnancies screened which did not subsequently result in a birth at a study center at $24^{0/7}$ to $27^{6/7}$ weeks.

Hi

Attached are the two SUPPORT papers for submission to NEJM. They will be submitted later this week.

Thanks to everyone for the **quick work in writing the papers** and the **patience and endurance** to conduct this important trial!!!

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-present).

Running head: Oxygen saturation and outcomes of prematurity

Key words: prematurity, extremely low birth weight infant, neonatal mortality, oxygen toxicity

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants when exposed to reduced oxygenation levels. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the *Eunice Kennedy Shriver* NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85-89% or 91-95%. The primary outcome was a composite of severe retinopathy of prematurity (threshold, retinopathy, surgical ophthalmologic intervention, or bevacizumab) and/or death before discharge from the hospital.

Results

The rate of severe retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28.3 vs 32.1%; RR 0.90; CI 0.76, 1.06; p= 0.21). Death occurred more frequently in the lower oxygen saturation target group (19.9 vs 16.2%; RR 1.27; CI 1.01, 1.60; p= 0.04) while severe retinopathy among survivors occurred less often in these infants (8.6 vs 17.9%; RR 0.52; CI 0.37, 0.73; p<0.001).

Conclusions

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcome of severe retinopathy or death but resulted in an increase in mortality and a substantial decrease in severe retinopathy among survivors. The increase in mortality is a major concern as lower saturation targeting is increasingly being advocated to prevent retinopathy of prematurity (clinicaltrials.gov NCT 00233324).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] This resulted in the practice of restricting oxygen supplementation, which was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6,7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy,[12] and other morbidities. Although a multicenter observational study[13] could not identify an association between PaO_2 levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations between lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3-5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery among very low birth weight infants was higher in infants cared for in neonatal intensive care units that used higher maximum oxygen saturation targets of $\geq$ 92% (3.3 $\pm$ 0.3%) or $\geq$98% (5.6 $\pm$ 1.1%) than in units with lower oxygen saturation targets (1.4 $\pm$ 0.2% and 3.1 $\pm$ 0.3%, respectively).[5] In a retrospective study comparing outcomes at five neonatal intensive care units, the incidence of severe retinopathy requiring ablation therapy was

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

27% in units where target saturations were 88-98% and only 6% in units where the target was 70-90%.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83-95% resulted in a substantial reduction in retinopathy but actual oxygen saturations achieved, mortality, and neurodevelopmental outcomes were not reported.[4,15,16] While data from these studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease retinopathy of prematurity, concerns remain about the safety of these oxygen saturation targets.

We conducted a 2 x 2 factorial design multicenter randomized controlled trial of two levels of oxygen saturation targeting and two ventilation approaches (continuous positive airway pressure initiated in the delivery room versus intubation with surfactant using two different protocol-driven pre-defined ventilatory strategies). The oxygen saturation component of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of the composite outcome of severe retinopathy of prematurity or death among infants of $24^{0/7}$ to $27^{6/7}$ weeks gestational age at birth. The ventilation part of this factorial design trial, which was used to control the ventilatory approach and test other hypotheses, will be reported separately.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at Research Triangle International, the independent data coordinating center, approved the trial.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Written informed consent was obtained from the parent or guardian of each participant before delivery.

Patients

Infants $24^{0/7}$ to $27^{6/7}$ weeks gestation for which a decision had been made to provide full resuscitation were eligible for enrollment at birth. Outborn infants and those known to have major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of sealed opaque envelopes to oxygen saturation targeting of 85-89% or 91-95% (the lower and higher oxygen saturation target groups, respectively) before birth using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88-92% for the targeted oxygen saturation ranges, with an offset of 3% (Masimo Radical Pulse Oximeter, Irvine, CA). A previous trial used a fixed 3% absolute oxygen saturation offset throughout the entire range of saturations to mask caregivers and separate oxygen saturations in premature infants.[17] The algorithm used in the current trial differed markedly as the oxygen saturation display transitioned and reverted to actual (non-skewed) values when less than 84% or higher than 96% in both treatment groups. An oxygen saturation display of 88% corresponded to actual oxygen saturations of 85% and 91% in the 85-89% and 91-95% target groups, respectively. Likewise, an

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

oxygen saturation display value of 92% corresponded to actual oxygen saturations of 89% and 95% in the 85-89% and 91-95% target groups, respectively. A display value of 96% corresponded to actual values of 93-96% and 96% in the low and high target groups, respectively. A display value of 84% corresponded to actual values of 84 and 84-87% in the low and high target groups, respectively. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours, whichever occurred first. Infants who weaned to room air, but who subsequently received oxygen supplementation before 36 weeks post-menstrual age, were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinical, not the research staff. Reports of displayed data by clinical center were provided quarterly to each center for feedback on displayed achieved oxygen targeting compliance. For the ventilation part of this 2 x 2 factorial design trial, participants were randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilatory strategy.

Assessments

Research nurses recorded all data using standardized definitions included in the trial's Manual of Operations. Data collection, excluding retinopathy of prematurity examinations, was completed at discharge. All surviving infants were followed by ophthalmologists trained in the diagnosis of retinopathy of prematurity. Examinations began by 33 weeks postmenstrual age and continued until the study endpoint or resolution was reached. Threshold retinopathy of prematurity (New

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Type 1 threshold per Early Treatment of Retinopathy Cooperative Group[18,19]) was coded if any of the following findings were present:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic intervention was coded if any of the following occurred: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, and vitrectomy. Resolution was defined as fully vascularized retinas or immature vessels in zone III for two consecutive examinations in each eye. The primary outcome was death before discharge and/or severe retinopathy defined as threshold retinopathy and/or surgical ophthalmologic surgery and/or bevacizumab treatment for retinopathy. Other outcomes recorded included only predefined clinical diagnoses, including assessment of oxygen need at 36 weeks postmenstrual age[20] and safety outcomes.

Statistical analysis

The analysis for the oxygen saturation part of this factorial trial compared the percent of infants in each treatment arm who developed the primary outcome of severe retinopathy or death. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks and 95% confidence intervals. Continuous outcomes were analyzed using mixed effects linear models to produce adjusted means and standard errors. Survival analysis using Cox regression compared mortality in the low and high oxygen saturation groups. In the analysis of all outcomes, adjustment was performed as pre-specified for stratification by center and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

gestational age as well as for familial clustering due to randomization of multiple births to the same treatment arm. To compare the actual oxygen saturation values in the two treatment arms, a median oxygen saturation value while on oxygen supplementation was determined for each infant. Those values were graphed by treatment group and the medians of the resulting distributions were compared using a Rank Sums test.

An absolute difference of 10% for the composite primary outcome between the two treatment groups was considered clinically important. The sample size calculations were based on the rate of death or threshold retinopathy of 50% in the Neonatal Research Network from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or BPD in the ventilation arm of this factorial trial). Based on an intracluster correlation of 0.12 in this outcome, the sample size was increased by a factor of 1.12 to allow for multiples to be randomized to the same treatment because this introduced a clustering effect into the design. The required sample size was increased by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to detect, with sufficient power, an interaction effect between the two factorial arms.

Intent-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. To account for multiple testing due to the co-primary outcomes in this factorial trial, a two-sided adjusted p value of less than 0.02 was considered to be statistically significant for the primary outcome of death or severe retinopathy. P values for secondary

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

outcomes are reported descriptively at the per-test level. Analyses of secondary outcomes did not include adjustment for multiple comparisons; however, for the planned secondary outcome comparisons by treatment, we would expect no more than three tests to have a p value of less than 0.05 on the basis of chance alone. Sub-group analyses were conducted within pre-specified gestational age strata on 36 pre-defined outcomes. Although these tests were not adjusted for multiple comparisons, we would expect no more than two tests per stratum to have p values of less than 0.05 based on chance alone.

An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at approximately 25%, 50%, and 75% of planned enrollment. In addition, the Data Safety and Monitoring Committee, upon request of the investigators, evaluated the oxygen saturation data to evaluate compliance with the protocol. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of these events.

RESULTS

1316 infants were enrolled between February 2005 and February 2009 (Figure 1). When 247 infants had been enrolled, enrollment was temporarily paused upon recommendation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Human Development Director because of concerns that displayed oxygen saturations often exceeded the targets Separation of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns because infants not requiring supplemental oxygen accounted for a large proportion of the high saturation levels maintained. Continued enrollment was approved.

The baseline characteristics of the two treatment groups were similar (Table 1). The primary outcome, severe retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28.3 vs 32.1%; RR 0.90; CI 0.76, 1.06; p= 0.21; Table 2). Death before discharge occurred in 130 of the 654 (19.9%) infants in the lower oxygen saturation group versus in 107 of the 662 (16.2%) infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; p= 0.04; number needed to harm 27). The distribution of the major causes of death did not differ significantly between the intervention and control groups (Appendix Table 1). Comparable results were observed for both gestational age strata. Survival analysis using Cox regression produced similar results (hazard ratio 1.32; CI 1.01, 1.72; p= 0.045) (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Severe retinopathy among survivors to discharge, transfer, or one year was decreased in the lower oxygen saturation group (8.6 vs 17.9%; RR 0.52; CI 0.37, 0.73; p< 0.001; number needed to treat 11). Oxygen use at 36 weeks was decreased in the lower oxygen saturation group (p=0.002) but bronchopulmonary dysplasia among survivors determined by the physiological oxygen saturation test at 36 weeks and the composite outcome of bronchopulmonary dysplasia/death by 36 weeks did not differ significantly between the treatment groups. Other pre-specified major outcomes did not differ significantly between the

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

two treatment groups (Table 2). While the trial was not powered to detect an interaction between the oxygen saturation and the ventilatory intervention, we prospectively agreed to evaluate such interactions and none were found.

The median oxygen saturation of infants in the two treatment groups while receiving oxygen supplementation differed substantially but, as expected, there was considerable overlap (Figure 3). These data indicate that actual median oxygen saturation levels were slightly higher than targeted in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Appendix Table 2). Other measures of resource utilization did not differ as well.

DISCUSSION

In this multicenter randomized trial we found that even though lower oxygen saturation targeting reduced severe retinopathy among survivors, it also increased the risk for in-hospital mortality. Longer follow-up will be important to determine the effects on functional visual outcome. Despite the absence of recent randomized trials and safety data and the increase in mortality when a restrictive oxygen supplementation was tested and practiced in the 1950s and 1960s, lower oxygen saturation targeting with the goal of reducing retinopathy of prematurity is becoming common practice.[3-5,15,16,21]

This is the largest randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results, in conjunction with previous reports, add to the concern that oxygen restriction may increase mortality in preterm infants. It is interesting and worrisome that the combined risk difference observed in the trials from the 1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.7% mortality increase in the lower oxygen saturation group that was observed in the current trial.

Randomized trials of oxygen restriction in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17,22] However, these trials aimed for saturations of 91-94% and 89-94% in the lower oxygen saturation group, which are closer to the targets of the higher saturation arm in the current trial. The increase in mortality in the current trial may be related either to the lower oxygen saturation targets or the use of oxygen restriction started soon after.

Meta-analyses of restriction of oxygen supplementation based on trials from the 1950s to the 1970s showed a large reduction in severe retinopathy (RR 0.19; CI 0.07, 0.50).[1,23] There have not been other randomized controlled trials of different oxygen targeting begun soon after birth. However, like most non-randomized studies[3-5,15,16], our trial confirmed that lower oxygen saturation targeting results in a large reduction of severe retinopathy among survivors.

There are several ongoing trials across the world that address the same intervention tested in the current trial and a planned prospective meta-analysis.[24] These trials use the same algorithm for

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

oxygen saturation targeting so their data will be combined in a meta-analysis to determine short and long term effects of oxygen saturation targeting.

In summary, oxygen saturation targeting in the 85-89% range did not affect the combined outcome of severe retinopathy/death but it increased mortality while substantially decreasing severe retinopathy among survivors. Neurodevelopmental assessments are being performed at 18-22 months corrected age. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years, but at the present time, caution should be exercised regarding oxygen targeting for premature infants in the low range tested as it may lead to increased mortality.

Legends

Figure 1. Flow chart of the screening, random assignment, and primary outcome. ROP denotes severe retinopathy of prematurity. The numbers excludes pregnancies screened which did not subsequently result in a birth at a study center at $24^{0/7}$ to $27^{6/7}$ weeks. The question marks in the ROP outcome boxes are for infants in whom the first ROP outcome could not be ascertained because of loss to follow up.

Figure 2. Survivor curve for mortality. Cox regression analysis indicated that there was a significantly higher hazard of death in the lower oxygen saturation group (hazard ratio 1.32; CI 1.01, 1.72; p= 0.045).

Figure 3. Median actual oxygen saturations while on oxygen supplementation for infants in each of the treatment groups. The medians of the distributions were significantly different based on a Rank Sums test ($p < 0.001$).

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-present).

Running head: Early CPAP versus Surfactant and outcomes of prematurity

Key words: CPAP, bronchopulmonary dysplasia, extremely low birth weight infant, neonatal mortality, surfactant

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths to 27 6/7ths weeks gestation. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilation strategy. Infants randomized to surfactant were to be intubated in the delivery room and received surfactant within 60 minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcomes of death or BPD, using the physiologic definition and death or BPD using the receipt of supplemental oxygen at 36 weeks were non-significantly reduced in the CPAP group compared to the surfactant group, when adjusted for gestational age, center and familial clustering (47.8% vs. 51.0%, Relative risk(RR) =0.95 (95% Confidence interval (CI) 0.85, 1.05) p=0.304, 48.7% vs. 54.1%, RR=0.91 (CI 0.82, 1.01), p=0.072). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001).

Conclusions: CPAP as used in this study is an effective evidence-based alternative to intubation and surfactant in preterm infants.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and death or BPD in

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

preterm infants.[12] Overall prophylactic surfactant has not been reported to significantly reduce BPD alone, whereas early compared with selective later surfactant has been associated with a decreased risk of chronic lung disease.[2] Surfactant not been found to significantly reduce subsequent neurodevelopmental impairment. [3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with respiratory distress documenting a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP. [4,5,6,7,8,9]

The recent trial by Morley et al randomized 610 infants from 25 0/7 to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H_20. CPAP infants were intubated if they met failure criteria.[10] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analysis[11]. There was a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006). The primary outcome of death or BPD at 36 weeks was non-significantly reduced in the CPAP arm, 33.9% vs 38.9%, (OR=0.58 to 1.12; P=0.19)

The SUPPORT trial was designed to compare early CPAP to early surfactant for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design. The results for the oximetry study will be reported

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

separately. The primary hypothesis of this trial was that in infants of 24 to 27 weeks gestation the use of early CPAP and a protocol driven strategy of limited ventilation with continuing CPAP in the NICU infants would result in an increased survival without BPD at 36 weeks using the physiologic definition compared to infants managed with surfactant within an hour of birth, and a subsequent conventional ventilator strategy.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol driven limited ventilation begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by a conventional ventilation strategy.

Infants were also randomized to a prospective comparison of a lower target SpO2 range (85% to 89%) with a higher more conventional target SpO2 range (91% to 95%) until the infant was 36 weeks or no longer received ventilatory support or oxygen.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a randomizing center, for whom a decision had been made to provide full resuscitation, and parental consent obtained. The infants were randomized within each center to two gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used for the delivery room administration of CPAP. CPAP or ventilation with PEEP, both at a recommended 5 cm H_2O, was utilized if the infant received positive pressure during resuscitation. CPAP was continued until admission to the NICU. CPAP infants were not to be intubated exclusively for surfactant administration in the DR. CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.[12]

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life, infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a $PaCO_2$ < 65 torr with a pH > 7.20, an SpO_2 > 88% with an FiO_2 < 50%, a mean airway pressure (MAP) < 10 cm H_2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations, CPAP infants were treated using NICU standard practice.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Surfactant Arm: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2 < 50$ torr and pH > 7.30, $FiO_2 \leq .35$ with a $SpO_2 \geq 88\%$, a MAP $\leq$ 8 cm H_2O, ventilator rate $\leq$ 20 bpm, an amplitude < 2X MAP if on HFV, and hemodynamically stable without evidence of clinically significant PDA. Once extubated, Surfactant infants were treated using NICU standard practice.

These criteria for both arms were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN baseline occurrence data (BPD 67%, NDI 61%). We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment because this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after discharge and before follow-up. Using a conservative 2% level of significance to account for the co-primary outcome of death or severe ROP in the SpO2 arm of this factorial

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

trial resulted in a required sample size of 1310 infants. This sample size was not powered to detect an interaction effect between the 2 factorial arms.

The Physiologic Definition of BPD assigned the diagnosis of BPD to any infant who received more than 30% oxygen at 36 weeks or who required positive pressure support, but required demonstration of oxygen dependence by an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks. [1314] Pre-specified secondary outcomes included the evaluation of BPD defined by the receipt of oxygen at 36 weeks.

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks post menstrual age (PMA) without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks with 95% confidence intervals. Continuous outcomes were analyzed using mixed effects linear models to produce adjusted means and standard errors. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering. To account for multiple testing due to the co-primary outcomes in this factorial trial, a two-sided p value of less than 0.02 was considered statistically significant for the primary outcome of death or BPD. P values for secondary outcomes are reported descriptively at the per-test level. Analyses of secondary outcomes did not include adjustment for multiple comparisons.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

The study was approved by Human Subjects Committees at all sites and RTI, the NRN data center. Parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled from February 2005 through February 2009. There were 565 infants enrolled in the lower gestational age strata (24 0/7 to 25 6/7 wks), and 751 in the higher strata 26 0/7 to 27 6/7 wks) (Figure). There were no significant differences for sex, birth weight, or race between the 2 treatment groups (Table 1).

Data regarding delivery room interventions is provided in Table 2. Fewer CPAP infants received positive pressure ventilation or epinephrine in the delivery room compared with the surfactant infants. Intubation in the DR was significantly decreased in the CPAP infants, and 32.9% of CPAP infants never received surfactant during their hospitalization.

The post delivery room outcomes are provided in Table 3. The primary outcome of death or BPD, using either the physiologic definition or the need for supplemental oxygen at 36 weeks

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

post menstrual age did not reach statistical significance when adjusted for gestational age, center and familial clustering as pre-specified.

Death during the hospitalization was non-significantly lower for the CPAP group overall. There was no significant difference in the occurrence of BPD among survivors to 36 weeks post menstrual age using either the Physiologic Definition or the receipt of oxygen at 36 weeks (Table 3).

There were no significant differences overall for death in the delivery room, length of stay, or days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, ($p=0.011$). There were no significant differences between the groups for air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but 2 infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who were intubated during their nursery course ($p<0.001$). There was a reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (7.2% vs. 13.2%, $p<0.001$) (Table 3). The incidence of severe retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[15] or need for surgical intervention or bevacizumab treatment for ROP among survivors was not different in the CPAP compared to the surfactant infants (Table 3). While the study was not powered to detect an interaction between the two interventions, we prospectively agreed to evaluate such interactions and none were found.

Strata Results: 24 – 25 weeks Gestation

CPAP infants in this stratum had a significantly lower mortality while hospitalized 23.9% vs. 32.1%, RR=0.74, (0.57, 0.98), p=0.034 (Appendix Table A1). Causes of death for this stratum are reported in Appendix Table A2.

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups in this stratum, 10.8% vs 10.2%. (Appendix Table A3).

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP initiated in the delivery room with early surfactant in very preterm infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. In a pilot trial we found that 100% of infants of 23 weeks gestation required intubation in the delivery room, and decided that such infants would unlikely be successfully treated with CPAP alone.[16] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[17]

Our trial differs from the recently reported trial of Morley et al[10~~10~~15] in that we randomized all eligible preterm infants irrespective of whether they demonstrated spontaneous breathing and enough respiratory distress to warrant intervention. We also included infants of 24 weeks gestation and compared CPAP and a protocol driven strategy of limited ventilation with infants

who were to receive surfactant within 1 hour of birth and a conventional strategy. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that units with the most success using CPAP also utilized a higher threshold for intubation and the initiation of mechanical ventilation. Error! Bookmark not defined.~~Error! Bookmark not defined.~~4,Error! Bookmark not defined.~~Error! Bookmark not defined.~~5,Error! Bookmark not defined.~~Error! Bookmark not defined.~~6 The infants who received surfactant were treated with a ventilation approach that was used by a majority of NRN units before the trial began. We believed that comparing these two methods would provide more clinically relevant results.

We prospectively identified safety outcomes that we chose to follow as investigators. These included: the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H_2O compared to the use of early surfactant.

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO_2 target range. The randomization resulted in a balance between the infants randomized to each intervention within the pre-specified gestational age strata (Figure, Table 1). While the study was not powered to detect an interaction between the 2 interventions, we prospectively agreed to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the primary outcomes. Data on survival without neurodevelopmental impairment at 18 to 22 months are currently accruing, and these results will be presented after all survivors have been assessed.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was not associated with any increase in death or BPD, or in any adverse neonatal outcomes. BPD using either the physiologic definition or the receipt of oxygen at 36 weeks was decreased but these differences were not statistically significant. We also noted a clinically significant 8.2% reduction in death in the CPAP infants of our 24 to 25 week stratum. While we did not postulate such a difference in the individual stratum this increased occurrence of death is cause for concern. The 565 infants in our 24 to 25 week stratum to our knowledge represent the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal steroids and a reduction in BPD or death by 36 weeks post menstrual age in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Conclusions:

Infants between 24 and 27 6/7ths weeks gestation assigned to treatment with CPAP have a non significant reduction in the incidence of death or BPD, with no demonstrable increase in any adverse neonatal outcome when compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth. Multiple secondary outcomes

including death in the immature stratum favored the CPAP group. CPAP as used in this study is an effective evidence-based alternative to intubation and surfactant in preterm infants.

Hi Rose
Marie made a few final edits, and I have reviewed. This is the final. Please check or modify the boilerplate as needed.
I hope that both manuscripts are ready for uploading.
Thanks for all your help
Neil

On 11/25/09 5:50 AM, "Gantz, Marie" <mgantz@rti.org> wrote:

Neil,

I corrected a few typos in this version of the paper (mostly I deleted extra spaces). I'm not sure I got all typos, though, so someone else might want to take a look. On page 16 in the Results you say "ROP among" which should either be "ROP among survivors" (which would be most accurate) or else "among" should be deleted. I also commented that the p values in the text sometimes use more digits than those in the tables (ex. 0.011 vs. 0.01) and I wonder if they need to be consistent. In the attached version of the tables I deleted where I had the source forms in parentheses, ex. "(SUPP03)" but there are still lots of abbreviations (DR, PPV, PDA, etc) that I wonder if we need to write out.

It's exciting to have this just about done!

FYI, I will be unavailable for a couple of hours this morning, but I will be back by noon if you need anything. I plan to take off on my 8 hour drive to Virginia before the Neoprom call but I will call in from the car (on mute to the extent possible).

Happy Thanksgiving, everyone!

On 11/30/09 9:32 AM, "Gantz, Marie" <mgantz@rti.org> wrote:

Hi Wally,

I have a few comments:

1) On page 12, instead of "Research Triangle International" RTI should be referred to as "RTI International."
2) On page 17, you removed the number of secondary outcomes analyzed for the population as a whole but left the number of secondary outcomes tested within the GA strata. I didn't know if you intended to delete one number and not the other.
3) You added "Present time in actual oxygen saturation range 84-96%, %" to Table 2, however, there are the following problems:
a. Instead of "Present time" I think the variable label should read "Percent of time" and it should be noted that only time on supplemental oxygen is included.
b. The numbers presented are mean +/- SD.
c. The values in the high SpO2 group should be 68.0 +/- 15.2
d. We decided to do an unadjusted test, thus the p value is unadjusted, not adjusted as noted the column label. Perhaps this information could be presented somewhere other than in Table 2?
4) Figure 1 legend states that "question marks in the ROP outcome boxes are for infants in whom the first ROP outcome could not be ascertained..." Did you mean to say "first ROP outcome" or "final ROP outcome?" I don't know what "first ROP outcome" means.

Thanks,
Marie

Hi,
I have attached a working draft of items for site compliance for the SUPPORT Trial. Once the Trial is up and running, RTI can assist us with on-site monitoring for compliance to insure adherence to the protocol. A medical person is needed along with the data center for compliance tracking visits. Please comment on the substance of the items to be looked at and feel free to contribute to the document.
Thanks
Happy Black Friday for all of the shoppers!

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-present).

Alpert Medical School of Brown University and Women & Infants Hospital of Rhode Island (U10 HD27904) - William Oh, MD; Angelita M. Hensman, RN BSN; Dan Gingras, RRT; Kim Francis, RN; Dawn Andrews, RN; Kristen Angela, RN.

Case Western Reserve University Rainbow Babies & Children's Hospital (U10 HD21364, GCRC M01 RR80) - Avroy A. Fanaroff, MD; Bonnie S. Siner, RN.

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

Abstract: 244

Manuscript: 2699

Running head: Early CPAP versus Surfactant and outcomes of prematurity

Key words: CPAP, bronchopulmonary dysplasia, extremely low birth weight infant, neonatal mortality, surfactant

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths to 27 6/7ths weeks gestation. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilation strategy. Infants randomized to surfactant were to be intubated in the delivery room and received surfactant within 60 minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcomes of death or BPD, using the physiologic definition and death or BPD using the need for supplemental oxygen at 36 weeks were non-significantly reduced in the CPAP group compared to the surfactant group, when adjusted for gestational age, center and familial clustering (47.8% vs. 51.0%, Relative risk(RR) =0.95 (95% Confidence interval (CI) 0.85, 1.05) p=0.304, 48.7% vs. 54.1%, RR=0.91 (CI 0.82, 1.01), p=0.072). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001).

Conclusions: CPAP as used in this study is an effective evidence-based alternative to intubation and surfactant in preterm infants.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and death or BPD in preterm infants.[12] Overall prophylactic surfactant has not been reported to significantly reduce BPD alone, whereas early compared with selective later surfactant has been associated with a decreased risk of chronic lung disease.[2] Surfactant not been found to significantly reduce

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

subsequent neurodevelopmental impairment.[3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with respiratory distress documenting a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP.[4,5,6,7,8,9]

The recent trial by Morley et al randomized 610 infants from 25 0/7 to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H_20. CPAP infants were intubated if they met failure criteria.[10] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analysis[11]. There was a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006). The primary outcome of death or BPD at 36 weeks was non-significantly reduced in the CPAP arm, 33.9% vs 38.9%, (OR=0.58 to 1.12; P=0.19)

The SUPPORT trial was designed to compare early CPAP to early surfactant for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design. The results for the oximetry study will be reported separately. The primary hypothesis of this trial was that in infants of 24 to 27 weeks gestation the use of early CPAP and a protocol driven strategy of limited ventilation with continuing CPAP in the NICU infants would result in an increased survival without BPD at 36 weeks using the

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

physiologic definition compared to infants managed with surfactant within an hour of birth, and a subsequent conventional ventilator strategy.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol driven limited ventilation begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by a conventional ventilation strategy.

Infants were also randomized to a prospective comparison of a lower target SpO2 range (85% to 89%) with a higher more conventional target SpO2 range (91% to 95%) until the infant was 36 weeks or no longer received ventilatory support or oxygen.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a randomizing center, for whom a decision had been made to provide full resuscitation, and parental consent obtained. The infants were randomized within each center to two gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used for the delivery room administration of CPAP. CPAP or ventilation with PEEP, both at a recommended 5 cm H_2O, was utilized if the infant received positive pressure during resuscitation. CPAP was continued until admission to the NICU. CPAP

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

infants were not to be intubated exclusively for surfactant administration in the DR. CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.[12]

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life, infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a $PaCO_2$ < 65 torr with a pH > 7.20, an SpO_2 > 88% with an FiO_2 < 50%, a mean airway pressure (MAP) < 10 cm H_2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations, CPAP infants were treated using NICU standard practice.

Surfactant Arm: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30, $FiO_2 \leq .35$ with a $SpO_2 \geq$88%, a MAP $\leq$ 8 cm H_2O, ventilator rate $\leq$ 20 bpm, an amplitude < 2X MAP if on HFV, and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

hemodynamically stable without evidence of clinically significant PDA. Once extubated, Surfactant infants were treated using NICU standard practice.

These criteria for both arms were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN baseline occurrence data (BPD 67%, NDI 61%). We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment because this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after discharge and before follow-up. Using a conservative 2% level of significance to account for the co-primary outcome of death or severe ROP in the SpO2 arm of this factorial trial, this resulted in a required sample size of 1310 infants. This sample size was not powered to detect an interaction effect between the 2 factorial arms.

The Physiologic Definition of BPD assigned the diagnosis of BPD to any infant who received more than 30% oxygen at 36 weeks or who required positive pressure support, but required

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

demonstration of oxygen dependence by an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks. [1314] Pre-specified secondary outcomes included the evaluation of BPD by the receipt of oxygen at 36 weeks.

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks post menstrual age (PMA) without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks with 95% confidence intervals. Continuous outcomes were analyzed using mixed effects linear models to produce adjusted means and standard errors. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering. To account for multiple testing due to the co-primary outcomes in this factorial trial, a two-sided p value of less than 0.02 was considered statistically significant for the primary outcome of death or BPD. P values for secondary outcomes are reported descriptively at the per-test level. Analyses of secondary outcomes did not include adjustment for multiple comparisons.

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

The study was approved by Human Subjects Committees at all sites and RTI, the NRN data center. Parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled from February 2005 through February 2009. There were 565 infants enrolled in the lower gestational age strata (24 0/7 to 25 6/7 wks), and 751 in the higher strata 26 0/7 to 27 6/7 wks) (Figure). There were no significant differences for sex, birth weight, or race between the 2 treatment groups (Table 1).

Data regarding delivery room interventions is provided in Table 2. Fewer CPAP infants received positive pressure ventilation or epinephrine in the delivery room compared with the surfactant infants. Intubation in the DR was significantly decreased in the CPAP infants, and 32.9% of CPAP infants never received surfactant during their hospitalization.

The post delivery room outcomes are provided in Table 3. The primary outcome of death or BPD, using either the physiologic definition or the need for supplemental oxygen at 36 weeks post menstrual age did not reach statistical significance when adjusted for gestational age, center and familial clustering as pre-specified.

Death during the hospitalization was non-significantly lower for the CPAP group overall. There was no significant difference in the occurrence of BPD among survivors to 36 weeks post

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

menstrual age using either the Physiologic Definition or the receipt of oxygen at 36 weeks (Table 3).

There were no significant differences overall for death in the delivery room, length of stay, or days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011). There were no significant differences between the groups for air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but 2 infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who were intubated during their nursery course (p<0.001). There was a reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (7.2% vs. 13.2%, p<0.001) (Table 3). The incidence of severe retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[15] or need for surgical intervention or bevacizumab treatment for ROP among was not different in the CPAP compared to the surfactant infants (Table 3). While the study was not powered to detect an interaction between the two interventions, we prospectively agreed to evaluate such interactions and none were found.

Strata Results: 24 – 25 weeks Gestation

CPAP infants in this strata had a significantly lower mortality while hospitalized 23.9% vs. 32.1%, RR=0.74, (0.57, 0.98), p=0.034 (Appendix Table A1). Causes of death for this strata are reported in Appendix Table A2.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups in this strata, 10.8% vs 10.2%. (Appendix Table A3).

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP initiated in the delivery room with early surfactant in very preterm infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. In a pilot trial we found that 100% of infants of 23 weeks gestation required intubation in the delivery room, and decided that such infants would unlikely be successfully treated with CPAP alone.[16] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[17]

Our trial differs from the recently reported trial of Morley et al [10~~10~~15] in that we randomized all eligible preterm infants irrespective of whether they demonstrated spontaneous breathing and enough respiratory distress to warrant intervention. We also included infants of 24 weeks gestation and compared CPAP and a protocol driven strategy of limited ventilation with infants who were to receive surfactant within 1 hour of birth and a conventional strategy. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that units with the most success using CPAP also utilized a higher threshold for intubation and the initiation of mechanical ventilation. ~~Bookmark not defined.~~4,Error! Bookmark not defined.~~Error! Bookmark not defined.~~5,Error! Bookmark not defined.~~Error! Bookmark not defined.~~6 The infants who received surfactant were treated with a ventilation approach that was used by a majority of NRN units before the trial began. We believed that comparing these two methods would provide more clinically relevant results.

We prospectively identified safety outcomes that we chose to follow as investigators. These included: the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H_2O compared to the use of early surfactant.

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO_2 target range. The randomization resulted in a balance between the infants randomized to each intervention within the pre-specified gestational age strata (Figure, Table 1). While the study was not powered to detect an interaction between the 2 interventions, we prospectively agreed to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the primary outcomes. Data on survival without neurodevelopmental impairment at 18 to 22 months are currently accruing, and these results will be presented after all survivors have been assessed.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was not associated with any increase in death or BPD, or in any adverse neonatal outcomes. BPD using either the physiologic definition or the need for oxygen at 36 weeks was decreased but these differences were not statistically significant. We also noted a clinically significant 8.2% reduction in death in

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

the CPAP infants of our 24 to 25 week stratum. While we did not postulate such a difference in the individual stratum this increased occurrence of death is cause for concern. The 565 infants in our 24 to 25 week stratum to our knowledge represent the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal steroids and a reduction in BPD or death by 36 weeks post menstrual age in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Conclusions:

Infants between 24 and 27 6/7ths weeks gestation assigned to treatment with CPAP have a non significant reduction in the incidence of death or BPD, with no demonstrable increase in any adverse neonatal outcome when compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth. Multiple secondary outcomes including death in the immature stratum favored the CPAP group. CPAP as used in this study is an effective evidence-based alternative to intubation and surfactant in preterm infants.

Wally
There is a problem with following sentence – I think you meant to say after birth – at present in both versions it ends as shown

"in the current trial may be related either to the lower oxygen saturation targets or the use of oxygen restriction

started soon after. "

Neil
Sorry for the delay- I have asked Kurt to designated 2 authors (not 3) for both papers. Ed and kurt served on the subcommittee. Vivek was the site PI. For other sites with a subcommittee member and a separate site PI, we noramlly allow a second, but not a third, author. I will also check wally's paper.

Thanks for pointing this out (sorry for the delay - I had computer problems which are now resolved).

Happy thanksgiving! And enjoy the grandkids!
Rose

Hi Rose
I would still like to know why we have 3 authors from Cincinnati?
Ed Donovan appears as an author and in the Boilerplate – this is interesting as other site NRN PIs such as Richard are not authors but appear in the boilerplate. To my knowledge Vivek was not on the subcommittee.
Please let me know why this is- I have agreed to the authorship methodology – but I do not agree with singling out this center, What am I missing?
Is this the same for Wally's paper?
I have not asked for much from the NRN – I would now respectfully request an answer.
Thanks
Neil

For the SUPPORT manuscripts, there are three requests for authorship which have been approved by the SUPPORT Subcommittee:
1. For Alabama, Ambal is requested to be an author based on his pivotal role in the trial at the highest recruiting site.
_xx__ yes ___no
2. For Rochester, Dale Phelps is recommended to be added to the oximetry paper due her role in training for ROP and source of ROP advice during the trial.
_xx__yes ____no
3. For Cincinnati, Ed Donovan is recommended to be added to the CPAP paper for his role in trial training and serving on the subcommittee until Kurt took over in 2006.
_xx__yes ____ no
I am sending this email to the non-SUPPORT subcommittee members for input as the SUPPORT SUBCOMMITTEE has already voted.
Please respond by November 25
Thanks

Neil,

Your tables are attached. I added differences in means for the continuous variables, and I rounded the p-values as Wally had done in his paper. I replaced ROP/death in table 3 with ROP among survivors, and I removed ROP/death from the GA strata tables for consistency. I also added a legend to figure 1 to correspond to what Wally had for his CONSORT figure.

Let me know if you need anything else.

There are 2 folks from Utah on the subcommittee (similar to mike and you on genomics).

The remainder of the items have been brought up by each site.

Rose

Subject: Re: VOTE:SUPPORT

Hi Rose,
I'm not sure I understand the reason for these changes. I thought authorship was based on our guidelines. Has it become a vote? And why are there 2 people from Utah for instance? I find this email a little unsettling since I thought this was all set and agreed upon.

Subject VOTE:SUPPORT

For the SUPPORT manuscripts, there are three requests for authorship which have

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

been approved by the SUPPORT Subcommittee:

1. For Alabama, Ambal is requested to be an author based on his pivotal role in the trial at the highest recruiting site.

___ yes ___no

2. For Rochester, Dale Phelps is recommended to be added to the oximetry paper due her role in training for ROP and source of ROP advice during the trial.

___yes ____no

3. For Cincinnati, Ed Donovan is recommended to be added to the CPAP paper for his role in trial training and serving on the subcommittee until Kurt took over in 2006.

___yes ____ no

I am sending this email to the non-SUPPORT subcommittee members for input as the SUPPORT SUBCOMMITTEE has already voted.

Please respond by November 25

Thanks

Rose

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Abstract: 244

Manuscript: 2699

Running head: Early CPAP versus Surfactant and outcomes of prematurity

Key words: CPAP, bronchopulmonary dysplasia, extremely low birth weight infant, neonatal mortality, surfactant

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths to 27 6/7ths weeks gestation. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilation strategy. Infants randomized to surfactant were to be intubated in the delivery room and received surfactant within 60 minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcomes of death or BPD, using the physiologic definition and death or BPD using the need for supplemental oxygen at 36 weeks were non-significantly reduced in the CPAP group compared to the surfactant group, when adjusted for gestational age, center and familial clustering (47.8% vs. 51.0%, Relative risk(RR) =0.95 (95% Confidence interval (CI) 0.85, 1.05) p=0.304, 48.7% vs. 54.1%, RR=0.91 (CI 0.82, 1.01), p=0.072). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001).

Conclusions: CPAP as used in this study is an effective evidence-based alternative to intubation and surfactant in preterm infants.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and death or BPD in preterm infants.[12] Overall prophylactic surfactant has not been reported to significantly reduce BPD alone, whereas early compared with selective later surfactant has been associated with a decreased risk of chronic lung disease.[2] Surfactant not been found to significantly reduce

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

subsequent neurodevelopmental impairment. [3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with respiratory distress documenting a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP. [4,5,6,7,8,9]

The recent trial by Morley et al randomized 610 infants from 25 0/7 to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H_20. CPAP infants were intubated if they met failure criteria.[10] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analysis[11]. There was a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006). The primary outcome of death or BPD at 36 weeks was non-significantly reduced in the CPAP arm, 33.9% vs 38.9%, (OR=0.58 to 1.12; P=0.19)

The SUPPORT trial was designed to compare early CPAP to early surfactant for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design. The results for the oximetry study will be reported separately. The primary hypothesis of this trial was that in infants of 24 to 27 weeks gestation the use of early CPAP and a protocol driven strategy of limited ventilation with continuing CPAP in the NICU infants would result in an increased survival without BPD at 36 weeks using the

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

physiologic definition compared to infants managed with surfactant within an hour of birth, and a subsequent conventional ventilator strategy.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol driven limited ventilation begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by a conventional ventilation strategy.

Infants were also randomized to a prospective comparison of a lower target SpO2 range (85% to 89%) with a higher more conventional target SpO2 range (91% to 95%) until the infant was 36 weeks or no longer received ventilatory support or oxygen.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a randomizing center, for whom a decision had been made to provide full resuscitation, and parental consent obtained. The infants were randomized within each center to two gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used for the delivery room administration of CPAP. CPAP or ventilation with PEEP, both at a recommended 5 cm H_2O, was utilized if the infant received positive pressure during resuscitation. CPAP was continued until admission to the NICU. CPAP

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

infants were not to be intubated exclusively for surfactant administration in the DR. CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.[12]

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life, infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a $PaCO_2$ < 65 torr with a pH > 7.20, an SpO_2 > 88% with an FiO_2 < 50%, a mean airway pressure (MAP) < 10 cm H_2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations, CPAP infants were treated using NICU standard practice.

Surfactant Arm: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30, $FiO_2 \leq .35$ with a $SpO_2 \geq 88\%$, a MAP $\leq$ 8 cm H_2O, ventilator rate $\leq$ 20 bpm, an amplitude < 2X MAP if on HFV, and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

hemodynamically stable without evidence of clinically significant PDA. Once extubated, Surfactant infants were treated using NICU standard practice.

These criteria for both arms were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN baseline occurrence data (BPD 67%, NDI 61%). We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment because this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after discharge and before follow-up. Using a conservative 2% level of significance to account for the co-primary outcome of death or severe ROP in the SpO2 arm of this factorial trial, this resulted in a required sample size of 1310 infants. This sample size was not powered to detect an interaction effect between the 2 factorial arms.

The Physiologic Definition of BPD assigned the diagnosis of BPD to any infant who received more than 30% oxygen at 36 weeks or who required positive pressure support, but required

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

demonstration of oxygen dependence by an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks. [1314] Pre-specified secondary outcomes included the evaluation of BPD by the receipt of oxygen at 36 weeks.

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks post menstrual age (PMA) without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks with 95% confidence intervals. Continuous outcomes were analyzed using mixed effects linear models to produce adjusted means and standard errors. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering. To account for multiple testing due to the co-primary outcomes in this factorial trial, a two-sided p value of less than 0.02 was considered statistically significant for the primary outcome of death or BPD. P values for secondary outcomes are reported descriptively at the per-test level. Analyses of secondary outcomes did not include adjustment for multiple comparisons.

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included

death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

The study was approved by Human Subjects Committees at all sites and RTI, the NRN data center. Parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled from February 2005 through February 2009. There were 565 infants enrolled in the lower gestational age strata (24 0/7 to 25 6/7 wks), and 751 in the higher strata 26 0/7 to 27 6/7 wks) (Figure). There were no significant differences for sex, birth weight, or race between the 2 treatment groups (Table 1).

Data regarding delivery room interventions is provided in Table 2. Fewer CPAP infants received positive pressure ventilation or epinephrine in the delivery room compared with the surfactant infants. Intubation in the DR was significantly decreased in the CPAP infants, and 32.9% of CPAP infants never received surfactant during their hospitalization.

The post delivery room outcomes are provided in Table 3. The primary outcome of death or BPD, using either the physiologic definition or the need for supplemental oxygen at 36 weeks post menstrual age did not reach statistical significance when adjusted for gestational age, center and familial clustering as pre-specified.

Death during the hospitalization was non-significantly lower for the CPAP group overall. There was no significant difference in the occurrence of BPD among survivors to 36 weeks post

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

menstrual age using either the Physiologic Definition or the receipt of oxygen at 36 weeks (Table 3).

There were no significant differences overall for death in the delivery room, length of stay, or days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011). There were no significant differences between the groups for air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but 2 infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who were intubated during their nursery course (p<0.001). There was a reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (7.2% vs. 13.2%, p<0.001) (Table 3). The incidence of severe retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[15] or need for surgical intervention or bevacizumab treatment for ROP among was not different in the CPAP compared to the surfactant infants (Table 3). While the study was not powered to detect an interaction between the two interventions, we prospectively agreed to evaluate such interactions and none were found.

Strata Results: 24 – 25 weeks Gestation

CPAP infants in this strata had a significantly lower mortality while hospitalized 23.9% vs. 32.1%, RR=0.74, (0.57, 0.98), p=0.034 (Appendix Table A1). Causes of death for this strata are reported in Appendix Table A2.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups in this strata, 10.8% vs 10.2%. (Appendix Table A3).

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP initiated in the delivery room with early surfactant in very preterm infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. In a pilot trial we found that 100% of infants of 23 weeks gestation required intubation in the delivery room, and decided that such infants would unlikely be successfully treated with CPAP alone.[16] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[17]

Our trial differs from the recently reported trial of Morley et al[10~~10~~15] in that we randomized all eligible preterm infants irrespective of whether they demonstrated spontaneous breathing and enough respiratory distress to warrant intervention. We also included infants of 24 weeks gestation and compared CPAP and a protocol driven strategy of limited ventilation with infants who were to receive surfactant within 1 hour of birth and a conventional strategy. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that units with the most success using CPAP also utilized a higher threshold for intubation and the initiation of mechanical ventilation. **Error! ~~Bookmark not defined.~~4,Error! Bookmark not defined.~~Error! Bookmark not defined.~~5,Error! Bookmark not defined.~~Error! Bookmark not defined.~~6 The infants who received surfactant were treated with a ventilation approach that was used by a majority of NRN units before the trial began. We believed that comparing these two methods would provide more clinically relevant results.

We prospectively identified safety outcomes that we chose to follow as investigators. These included: the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H_2O compared to the use of early surfactant.

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO_2 target range. The randomization resulted in a balance between the infants randomized to each intervention within the pre-specified gestational age strata (Figure, Table 1). While the study was not powered to detect an interaction between the 2 interventions, we prospectively agreed to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the primary outcomes. Data on survival without neurodevelopmental impairment at 18 to 22 months are currently accruing, and these results will be presented after all survivors have been assessed.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was not associated with any increase in death or BPD, or in any adverse neonatal outcomes. BPD using either the physiologic definition or the need for oxygen at 36 weeks was decreased but these differences were not statistically significant. We also noted a clinically significant 8.2% reduction in death in

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

the CPAP infants of our 24 to 25 week stratum. While we did not postulate such a difference in the individual stratum this increased occurrence of death is cause for concern. The 565 infants in our 24 to 25 week stratum to our knowledge represent the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal steroids and a reduction in BPD or death by 36 weeks post menstrual age in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Conclusions:

Infants between 24 and 27 6/7ths weeks gestation assigned to treatment with CPAP have a non significant reduction in the incidence of death or BPD, with no demonstrable increase in any adverse neonatal outcome when compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth. Multiple secondary outcomes including death in the immature stratum favored the CPAP group. CPAP as used in this study is an effective evidence-based alternative to intubation and surfactant in preterm infants.

How did they know whether the baby had majority saturation >=90% based on the altered oximeters? An actual saturation of 90% would have corresponded to a display value of 87 or 93 depending on whether the low or high oximeter was used.

It was decided based on their status at 36 weeks--they were on the Massimos at that time. However, as part of the physiologic reduction, all babies were put on a unit (nonblinded, nonskewed) oximeter for a baseline period, then reduced if continuing to meet the criteria for reduction. There should have been no difference in failure rate in the babies who were in the high sat group vs. the low sat group.

Are we all clear about this? The study oximeter was in place on the 36 week date (we removed it the next day). Whether or not an infant is reduced using the Physiologic Definition is determine by the effective oxygen on that 36 week day. We had a week after the 36 week date to perform the physiologic definition.

Dr. Tyson, I believe that Dr. Kennedy's assessment is correct. All the centers should have done it the same way. The Masimo oximeter stayed on the infant through the 36 week date and BPD criteria is on the 36 week date. The reduction is to be done within 1 week of the 36+1 week date. 1. Oxygen by NC <27% effective oxygen and the majority of saturations greater than or equal to 90% in the prior 24 hours is eligible for reduction. 2. Oxygen by NC 27-30% effective oxygen and the majority of saturations greater than or equal to 96% in the prior 2 hours are eligible for reduction. 3. Room air NC at any liter flow is eligible for reduction. The Masimo oximeters displayed a target of 88-92% on both the high and low range altered oximeters. Low range was actual 85-89% target and the high range was actual 91-95% target. Since the study monitor was removed from the infant on the 36+1 date the reductions were done on the unit monitors and this should be consistent with all the centers. I have the MOP in the office of both the Support and BPD if you need them. I hope that this helps.

Subject: Re: Support information.
As I understand it, they used a non-study sat momitor for the oxygen challenge so that was done the same way in both groups. The difference between the O2 sat groups was that the criteria for deciding who qualified for the challenge were based on the amount of O2 needed to achieve the study targets. Presumably babies in the high sat group would be more likely to get a challenge, and therefore slightly more likely to fail, than babies in the low sat group.

Subject: Support information.

Kathleen, In the MOP on page 16-1 it states that the information is collected through 36 weeks and on page C-1 we used the BPD MOP for the reduction. We took the Masimo off the patients the day after their 36 week date then according to the BPD MOP we did the reduction if they qualified within 1 week. Therefore the information to determine if the patient qualified for the reduction was from the Masimo on the 36 week date and the reduction was done using the saturations from the unit monitors within a week. Please let me know if you have any further questions. Patti

Rose
I vote yes for all
At some point however we do need to revisit the # of authors per site, I don't remember the current Publication policy, but the one I am familiar with did state after the RCT Subcommittee it should be one author per site. Maybe I am wrong???

For the SUPPORT manuscripts, there are three requests for authorship which have been approved by the SUPPORT Subcommittee:

1. For Alabama, Ambal is requested to be an author based on his pivotal role in the trial at the highest recruiting site.
   ___ yes ___no
2. For Rochester, Dale Phelps is recommended to be added to the oximetry paper due her role in training for ROP and source of ROP advice during the trial.
   ___yes ____no
3. For Cincinnati, Ed Donovan is recommended to be added to the CPAP paper for his role in trial training and serving on the subcommittee until Kurt took over in 2006.
   ___yes ____ no

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

I am sending this email to the non-SUPPORT subcommittee members for input as the SUPPORT SUBCOMMITTEE has already voted.
Please respond by November 25
Thanks
Rose

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Running head: Early CPAP versus Surfactant and outcomes of prematurity

Key words: CPAP, bronchopulmonary dysplasia, extremely low birth weight infant, neonatal mortality, surfactant

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths to 27 6/7ths weeks gestation. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilation strategy. Infants randomized to surfactant were to be intubated in the delivery room and received surfactant within 60 minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcomes of death or BPD, using the physiologic definition and death or BPD using the need for supplemental oxygen at 36 weeks were non-significantly reduced in the CPAP group compared to the surfactant group, when adjusted for gestational age, center and familial clustering (47.8% vs. 51.0%, Relative risk(RR) =0.95 (95% Confidence interval (CI) 0.85, 1.05) p=0.304, 48.7% vs. 54.1%, RR=0.91 (CI 0.82, 1.01), p=0.072). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001).

Conclusions: CPAP as used in this study is an effective evidence-based alternative to intubation and surfactant in preterm infants.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and death or BPD in preterm infants.[12] Overall prophylactic surfactant has not been reported to significantly reduce BPD alone, whereas early compared with selective later surfactant has been associated with a decreased risk of chronic lung disease.[2] Surfactant not been found to significantly reduce subsequent neurodevelopmental impairment.[3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with respiratory distress documenting a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP.[4,5,6,7,8,9]

The recent trial by Morley et al randomized 610 infants from 25 0/7 to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H_20. CPAP infants were intubated if they met failure criteria.[10] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analysis[11]. There was a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006). The primary outcome of death or BPD at 36 weeks was non-significantly reduced in the CPAP arm, 33.9% vs 38.9%, (OR=0.58 to 1.12; P=0.19)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The SUPPORT trial was designed to compare early CPAP to early surfactant for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design. The results for the oximetry study will be reported separately. The primary hypothesis of this trial was that in infants of 24 to 27 weeks gestation the use of early CPAP and a protocol driven strategy of limited ventilation with continuing CPAP in the NICU infants would result in an increased survival without BPD at 36 weeks using the physiologic definition compared to infants managed with surfactant within an hour of birth, and a subsequent conventional ventilator strategy.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol driven limited ventilation begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by a conventional ventilation strategy.

Infants were also randomized to a prospective comparison of a lower target SpO2 range (85% to 89%) with a higher more conventional target SpO2 range (91% to 95%) until the infant was 36 weeks or no longer received ventilatory support or oxygen.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a randomizing center, for whom a decision had been made to provide full resuscitation, and parental consent obtained. The infants were randomized within

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

each center to two gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used for the delivery room administration of CPAP. CPAP or ventilation with PEEP, both at a recommended 5 cm H_2O, was utilized if the infant received positive pressure during resuscitation. CPAP was continued until admission to the NICU. CPAP infants were not to be intubated exclusively for surfactant administration in the DR. CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.[12]

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life, infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a $PaCO_2$ < 65 torr with a pH > 7.20, an SpO_2 > 88% with an FiO_2 < 50%, a mean airway pressure (MAP) < 10 cm H_2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations, CPAP infants were treated using NICU standard practice.

Surfactant Arm: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2 < 50$ torr and pH > 7.30, $FiO_2 \leq .35$ with a $SpO_2 \geq 88\%$, a MAP $\leq$ 8 cm H_2O, ventilator rate $\leq$ 20 bpm, an amplitude < 2X MAP if on HFV, and hemodynamically stable without evidence of clinically significant PDA. Once extubated, Surfactant infants were treated using NICU standard practice.

These criteria for both arms were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN baseline occurrence data (BPD 67%, NDI 61%). We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment because this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for

attrition after discharge and before follow-up. Using a conservative 2% level of significance to account for the co-primary outcome of death or severe ROP in the SpO2 arm of this factorial trial, this resulted in a required sample size of 1310 infants. This sample size was not powered to detect an interaction effect between the 2 factorial arms.

The Physiologic Definition of BPD assigned the diagnosis of BPD to any infant who received more than 30% oxygen at 36 weeks or who required positive pressure support, but required demonstration of oxygen dependence by an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks. [1314] Pre-specified secondary outcomes included the evaluation of BPD by the receipt of oxygen at 36 weeks.

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks post menstrual age (PMA) without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks with 95% confidence intervals. Continuous outcomes were analyzed using mixed effects linear models to produce adjusted means and standard errors. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering. To account for multiple testing due to the co-primary outcomes in this factorial trial, a two-sided p value of less than 0.02 was considered statistically significant for the primary outcome of death or BPD. P values for secondary

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

outcomes are reported descriptively at the per-test level. Analyses of secondary outcomes did not include adjustment for multiple comparisons.

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

The study was approved by Human Subjects Committees at all sites and RTI, the NRN data center. Parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled from February 2005 through February 2009. There were 565 infants enrolled in the lower gestational age strata (24 0/7 to 25 6/7 wks), and 751 in the higher strata 26 0/7 to 27 6/7 wks) (Figure). There were no significant differences for sex, birth weight, or race between the 2 treatment groups (Table 1).

Data regarding delivery room interventions is provided in Table 2. Fewer CPAP infants received positive pressure ventilation or epinephrine in the delivery room compared with the surfactant infants. Intubation in the DR was significantly decreased in the CPAP infants, and 32.9% of CPAP infants never received surfactant during their hospitalization.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The post delivery room outcomes are provided in Table 3. The primary outcome of death or BPD, using either the physiologic definition or the need for supplemental oxygen at 36 weeks post menstrual age did not reach statistical significance when adjusted for gestational age, center and familial clustering as pre-specified.

Death during the hospitalization was non-significantly lower for the CPAP group overall. There was no significant difference in the occurrence of BPD among survivors to 36 weeks post menstrual age using either the Physiologic Definition or the receipt of oxygen at 36 weeks (Table 3).

There were no significant differences overall for death in the delivery room, length of stay, or days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, ($p=0.011$). There were no significant differences between the groups for air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but 2 infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who were intubated during their nursery course ($p<0.001$). There was a reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (7.2% vs. 13.2%, $p<0.001$) (Table 3). The incidence of severe retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[15] or need for surgical intervention or bevacizumab treatment for ROP among was not different in the CPAP compared to the surfactant infants (Table 3). While the study was not powered to detect an interaction

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

between the two interventions, we prospectively agreed to evaluate such interactions and none were found.

Strata Results: 24 – 25 weeks Gestation

CPAP infants in this strata had a significantly lower mortality while hospitalized 23.9% vs. 32.1%, RR=0.74, (0.57, 0.98), p=0.034 (Appendix Table A1). Causes of death for this strata are reported in Appendix Table A2.

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups in this strata, 10.8% vs 10.2%. (Appendix Table A3).

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP initiated in the delivery room with early surfactant in very preterm infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. In a pilot trial we found that 100% of infants of 23 weeks gestation required intubation in the delivery room, and decided that such infants would unlikely be successfully treated with CPAP alone.[16] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[17]

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our trial differs from the recently reported trial of Morley et al[10][15] in that we randomized all eligible preterm infants irrespective of whether they demonstrated spontaneous breathing and enough respiratory distress to warrant intervention. We also included infants of 24 weeks gestation and compared CPAP and a protocol driven strategy of limited ventilation with infants who were to receive surfactant within 1 hour of birth and a conventional strategy. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that units with the most success using CPAP also utilized a higher threshold for intubation and the initiation of mechanical ventilation.[Error! Bookmark not defined.Error! Bookmark not defined.4,Error! Bookmark not defined.Error! Bookmark not defined.5,Error! Bookmark not defined.Error! Bookmark not defined.6] The infants who received surfactant were treated with a ventilation approach that was used by a majority of NRN units before the trial began. We believed that comparing these two methods would provide more clinically relevant results.

We prospectively identified safety outcomes that we chose to follow as investigators. These included: the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H_2O compared to the use of early surfactant.

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO_2 target range. The randomization resulted in a balance between the infants randomized to each intervention within the pre-specified gestational age strata (Figure, Table 1). While the study was not powered to detect an

interaction between the 2 interventions, we prospectively agreed to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the primary outcomes. Data on survival without neurodevelopmental impairment at 18 to 22 months are currently accruing, and these results will be presented after all survivors have been assessed.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was not associated with any increase in death or BPD, or in any adverse neonatal outcomes. BPD using either the physiologic definition or the need for oxygen at 36 weeks was decreased but these differences were not statistically significant. We also noted a clinically significant 8.2% reduction in death in the CPAP infants of our 24 to 25 week stratum. While we did not postulate such a difference in the individual stratum this increased occurrence of death is cause for concern. The 565 infants in our 24 to 25 week stratum to our knowledge represent the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal steroids and a reduction in BPD or death by 36 weeks post menstrual age in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Conclusions:

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Infants between 24 and 27 6/7ths weeks gestation assigned to treatment with CPAP have a non significant reduction in the incidence of death or BPD, with no demonstrable increase in any adverse neonatal outcome when compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth. Multiple secondary outcomes including death in the immature stratum favored the CPAP group. CPAP as used in this study is an effective evidence-based alternative to intubation and surfactant in preterm infants.

Running head: Oxygen saturation and outcomes of prematurity

Key words: prematurity, extremely low birth weight infant, neonatal mortality, oxygen toxicity

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants when exposed to reduced oxygenation levels. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the *Eunice Kennedy Shriver* NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85-89% or 91-95%. The primary outcome was a composite of severe retinopathy of prematurity (threshold, retinopathy, surgical ophthalmologic intervention, or bevacizumab) and/or death before discharge from the hospital.

Results

The rate of severe retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28.3 vs 32.1%; RR 0.90; CI 0.76, 1.06; p= 0.20). Death occurred more frequently in the lower oxygen saturation target group (19.9 vs 16.2%; RR 1.27; CI 1.01, 1.60; p= 0.04) while severe retinopathy among survivors occurred less often in these infants (8.6 vs 17.9%; RR 0.52; CI 0.37, 0.73; p<0.001).

Conclusions

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcome of severe retinopathy/death but resulted in an increase in mortality that and a substantial decrease in severe retinopathy among survivors. The increase in mortality is a major concern as lower saturation targeting is increasingly being advocated to prevent retinopathy of prematurity (clinicaltrials.gov NCT 00233324).

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] This resulted in the practice of restricting oxygen supplementation, which was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6,7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy,[12] and other morbidities. Although a multicenter observational study[13] could not identify an association between PaO_2 levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations between lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3-5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery among very low birth weight infants was higher in infants cared for in neonatal intensive care units that used higher maximum oxygen saturation targets of $\geq$ 92% (3.3 $\pm$ 0.3%) or $\geq$98% (5.6 $\pm$ 1.1%) than in units with lower oxygen saturation targets (1.4 $\pm$ 0.2% and 3.1 $\pm$ 0.3%, respectively).[5] In a retrospective study comparing outcomes at five neonatal intensive care units, the incidence of severe retinopathy requiring ablation therapy was

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

27% in units where target saturations were 88-98% and only 6% in units where the target was 70-90%.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83-95% resulted in a substantial reduction in retinopathy but actual oxygen saturations achieved, mortality, and neurodevelopmental outcomes were not reported.[4,15,16] While data from these recent prospective observational studies, retrospective studies, or controlled studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease the incidence of retinopathy of prematurity, an increase in serious adverse effects or deaths were not reported.

We conducted a 2 x 2 factorial design multicenter randomized controlled trial of two levels of oxygen saturation targeting and continuous positive airway pressure initiated in the delivery room versus intubation with surfactant using two different protocol-driven pre-defined ventilatory strategies. The oxygen saturation component of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of the composite outcome of severe retinopathy of prematurity or death among infants of $24^{0/7}$ to $27^{6/7}$ weeks gestational age at birth. The ventilation part of this factorial design trial, which was used to control the ventilatory approach and test other hypotheses, will be reported separately.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at Research Triangle International, the independent data coordinating center, approved the trial.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Written informed consent was obtained from the parent or guardian of each participant before delivery.

Patients

Infants $24^{0/7}$ to $27^{6/7}$ weeks gestation for which a decision had been made to provide full resuscitation were eligible for enrollment at birth. Outborn infants and those known to have major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of sealed opaque envelopes to oxygen saturation targeting of 85-89% or 91-95% (the lower and higher oxygen saturation target groups, respectively) before birth using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88-92% for the targeted oxygen saturation ranges, with an offset of 3% (Masimo Radical Pulse Oximeter, Irvine, CA). A similar algorithm was used to mask caregivers and separate oxygen saturations in premature infants.[17] Thus, an oxygen saturation display of 88% corresponded to actual oxygen saturations of 85% and 91% in the 85-89% and 91-95% target groups, respectively. Likewise, an oxygen saturation display value of 92% corresponded to actual oxygen saturations of 89% and 95% in the 85-89% and 91-95% target groups, respectively. A display value of 96% corresponded to actual values of 93-96% and 96% in the low and high target groups, respectively. A display

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

value of 84% corresponds to actual values of 87 and 84-87% in the low and high target groups, respectively. The oxygen saturation display transitioned and reverted to actual (non-skewed) values when less than 84% or higher than 96% in both treatment groups. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours, whichever occurred first. Infants who weaned to room air, but who subsequently received oxygen supplementation before 36 weeks post-menstrual age, were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinical, not the research staff. Reports of displayed data by clinical center were provided quarterly to each center for feedback on displayed achieved oxygen targeting performance. For the ventilation part of this 2 x 2 factorial design trial, participants were randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilatory strategy.

Assessments

Research nurses recorded all data using standardized definitions included in the trial Manual of Operations. Data collection, excluding retinopathy of prematurity examinations, was completed at discharge. All surviving infants were followed by ophthalmological specialists familiar with retinopathy of prematurity. Examinations began by 33 weeks postmenstrual age and continued until the study endpoint or resolution was reached. Threshold retinopathy of prematurity (New

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Type 1 threshold per Early Treatment of Retinopathy Cooperative Group[18,19]) was coded if any of the following findings were present:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic intervention was coded if any of the following were present: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, and vitrectomy. Resolution was defined as fully vascularized retinas or immature vessels in zone III for two consecutive examinations in each eye. The primary outcome was death before discharge and/or severe retinopathy defined as threshold retinopathy and/or surgical ophthalmologic surgery and/or bevacizumab treatment for retinopathy. Other outcomes recorded included only predefined clinical diagnoses, including assessment of oxygen need at 36 weeks postmenstrual age[20] and safety outcomes.

Statistical analysis

The analysis for the oxygen saturation part of this factorial trial compared the percent of infants in each treatment arm who developed the primary outcome of severe retinopathy or death. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks and 95% confidence intervals. Continuous outcomes were analyzed using mixed effects linear models to produce adjusted means and standard errors. Survival analysis using Cox regression compared mortality in the low and high oxygen saturation groups. In the analysis of all outcomes, adjustment was performed as pre-specified for stratification by center and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

gestational age as well as for familial clustering due to randomization of multiple births to the same treatment arm. To compare the actual oxygen saturation values in the two treatment arms, a median oxygen saturation value while on oxygen supplementation was determined for each infant. Those values were graphed by treatment group and the medians of the resulting distributions were compared using a Rank Sums test.

An absolute difference of 10% for the composite primary outcome between the two treatment groups was considered clinically important. The sample size calculations were based on the rate of death or threshold retinopathy of 50% in the Neonatal Research Network from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or BPD in the ventilation arm of this factorial trial). Based on an intracluster correlation of 0.12 in this outcome, the sample size was increased by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because this introduced a clustering effect into the design. The required sample size was increased by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to detect, with sufficient power, an interaction effect between the two factorial arms.

Intent-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. To account for multiple testing due to the co-primary outcomes in this factorial trial, a two-sided adjusted p value of less than 0.02 was considered to be statistically significant for the primary outcome of death or severe retinopathy. P values for secondary

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

outcomes are reported descriptively at the per-test level. Analyses of secondary outcomes did not include adjustment for multiple comparisons; however, for the 46 planned secondary outcome comparisons by treatment, we would expect no more than three tests to have a p value of less than 0.05 on the basis of chance alone. Sub-group analyses were conducted within pre-specified gestational age strata on 36 pre-defined outcomes. Although these tests were not adjusted for multiple comparisons, we would expect no more than two tests per stratum to have p values of less than 0.05 based on chance alone.

An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at approximately 25%, 50%, and 75% of planned enrollment. In addition, the Data Safety and Monitoring Committee, upon request of the investigators, evaluated the oxygen saturation data to evaluate compliance with the protocol. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of these events.

RESULTS

1316 infants were enrolled between February 2005 and February 2009 (Figure 1). When 247 infants had been enrolled, enrollment was temporarily paused upon recommendation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Human Development Director because of concerns that displayed oxygen saturations often exceeded the targets Separation of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns because infants not requiring supplemental oxygen accounted for a large proportion of the high saturation levels maintained. Continued enrollment was approved.

The baseline characteristics of the two treatment groups were similar (Table 1). The primary outcome, severe retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28.3 vs 32.1%; RR 0.90; CI 0.76, 1.06; p= 0.20; Table 2). Death before discharge occurred in 130 of the 654 (19.9%) infants in the lower oxygen saturation group versus in 107 of the 662 (16.2%) infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; p= 0.04; number needed to harm 27). The distribution of the major causes of death did not differ significantly between the intervention and control groups (Appendix Table 1). Comparable results were observed for both gestational age strata. Survival analysis using Cox regression produced similar results (hazard ratio 1.32; CI 1.01, 1.72; p= 0.045) (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Severe retinopathy among survivors to discharge, transfer, or one year was decreased in the lower oxygen saturation group (8.6 vs 17.9%; RR 0.52; CI 0.37, 0.73; p< 0.001; number needed to treat 11). Oxygen use at 36 weeks was decreased in the lower oxygen saturation group (p=0.002) but bronchopulmonary dysplasia among survivors determined by the physiological oxygen saturation test at 36 weeks and the composite outcome of bronchopulmonary dysplasia/death by 36 weeks did not differ significantly between the treatment groups. Other pre-specified major outcomes did not differ significantly between the

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

two treatment groups (Table 2). While the trial was not powered to detect an interaction between the oxygen saturation and the ventilatory intervention, we prospectively agreed to evaluate such interactions and none were found.

The median oxygen saturation of infants in the two treatment groups while receiving oxygen supplementation differed substantially but, as expected, there was substantial overlap (Figure 3). These data indicate that actual median oxygen saturation levels were slightly higher than targeted in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Appendix Table 2). Other measures of resource utilization did not differ as well.

DISCUSSION

In this multicenter randomized trial we found that even though lower oxygen saturation targeting reduced severe retinopathy among survivors, it also increased the risk for in-hospital mortality. Longer follow-up will be important to determine the effects on functional visual outcome. Despite the absence of recent randomized trials and safety data and the increase in mortality when a restrictive oxygen supplementation was tested and practiced in the 1950s and 1960s, lower oxygen saturation targeting with the goal of reducing retinopathy of prematurity is becoming common practice.[3-5,15,16,21]

This is the largest randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results, in conjunction with previous reports, add to the concern that oxygen restriction may increase mortality in preterm infants. It is interesting and worrisome that the combined risk difference observed in the trials from the 1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.7% mortality increase in the lower oxygen saturation group that was observed in the current trial.

Randomized trials of oxygen restriction in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17,22] However, these trials aimed for saturations of 91-94% and 89-94% in the lower oxygen saturation group, which are closer to the targets of the higher saturation arm in the current trial. The lower oxygen saturation targets or the use of oxygen restriction from birth in the current trial may be related to the adverse outcome.

Meta-analyses of restriction of oxygen supplementation based on trials from the 1950s to the 1970s showed a large reduction in severe retinopathy (RR 0.19; CI 0.07, 0.50).[1,23] There have not been other randomized controlled trials of different oxygen targeting starting soon after birth. However, like most non-randomized studies[3-5,15,16], our trial confirmed that lower oxygen saturation targeting results in a large reduction of severe retinopathy among survivors.

There are several ongoing trials across the world that address the same intervention tested in the current trial and a planned prospective meta-analysis.[24] These trials use the same algorithm for

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

oxygen saturation targeting so their data will be combined in a meta-analysis to determine short and long term effects of oxygen saturation targeting.

In summary, oxygen saturation targeting in the 85-89% range did not affect the combined outcome of severe retinopathy/death but it increased mortality while substantially decreasing severe retinopathy among survivors. Neurodevelopmental assessments are being performed at 18-22 months corrected age. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years, but at the present time, caution should be exercised regarding oxygen targeting for premature infants in the low range tested as it may lead to increased mortality.

Appendix Table 2. Other Outcomes in a Randomized Trial of Lower versus Higher Oxygen Saturation Targets in Extremely Low Birth Weight Infants

Outcome	Lower Saturation Group	Higher Saturation Group	Adjusted P value‡
Length of stay any hospital, (days) m+SE*	104.5 ± 2.0	106.4 ± 2.0	0.45
Length of stay at study hospital, (days) m+SE*	99.8 ± 2.0	103.0 ± 2.0	0.22
Duration of mechanical ventilation, (days) m+SE†	25.5 ± 1.1	26.9 ± 1.0	0.30
Duration of oxygen supplementation, (days) m+SE†	59.8 ± 1.6	67.4 ± 1.5	0.0002
Continuous positive airway pressure, (days) m+SE†	17.1 ± 0.6	17.0 ± 0.6	0.94
Nasal synchronized intermittent mandatory ventilation, (days) m+SE†	3.3 ± 0.3	3.8 ± 0.3	0.14
Alive off mechanical ventilation by day 14, (days) – no. (%)	332/644 (51.6)	326/655 (49.8)	0.86
Alive off mechanical ventilation by day 7, (days) – no. (%)	351/648 (54.2)	329/659 (49.9)	0.27

*Among survivors to discharge, transfer or one year; maximum value is 366 days

†Among survivors to discharge, transfer or 120 days; maximum value is 120 days

‡Adjusted for stratification factors (study center, gestational age group) as well as for familial clustering

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants when exposed to reduced oxygenation levels. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the *Eunice Kennedy Shriver* NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85-89% or 91-95%. The primary outcome was a composite of severe retinopathy of prematurity (threshold, retinopathy, surgical ophthalmologic intervention, or bevacizumab) and/or death before discharge from the hospital.

Results

The rate of severe retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28.3 vs 32.1%; RR 0.90; CI 0.76, 1.06; p= 0.20). Death occurred more frequently in the lower oxygen saturation target group (19.9 vs 16.2%; RR 1.27; CI 1.01, 1.60; p= 0.04) while severe retinopathy among survivors occurred less often in these infants (8.6 vs 17.9%; RR 0.52; CI 0.37, 0.73; p<0.001).

Conclusions

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcome of severe retinopathy/death but resulted in an increase in mortality that and a substantial decrease in severe retinopathy among survivors. The increase in mortality is a major concern as lower saturation targeting is increasingly being advocated to prevent retinopathy of prematurity (clinicaltrials.gov NCT 00233324).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] This resulted in the practice of restricting oxygen supplementation, which was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6,7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy,[12] and other morbidities. Although a multicenter observational study[13] could not identify an association between PaO_2 levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations between lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3-5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery among very low birth weight infants was higher in infants cared for in neonatal intensive care units that used higher maximum oxygen saturation targets of $\geq$ 92% (3.3 $\pm$ 0.3%) or $\geq$98% (5.6 $\pm$ 1.1%) than in units with lower oxygen saturation targets (1.4 $\pm$ 0.2% and 3.1 $\pm$ 0.3%, respectively).[5] In a retrospective study comparing outcomes at five neonatal intensive care units, the incidence of severe retinopathy requiring ablation therapy was

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

27% in units where target saturations were 88-98% and only 6% in units where the target was 70-90%.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83-95% resulted in a substantial reduction in retinopathy but actual oxygen saturations achieved, mortality, and neurodevelopmental outcomes were not reported.[4,15,16] While data from these recent prospective observational studies, retrospective studies, or controlled studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease the incidence of retinopathy of prematurity, an increase in serious adverse effects or deaths were not reported.

We conducted a 2 x 2 factorial design multicenter randomized controlled trial of two levels of oxygen saturation targeting and continuous positive airway pressure initiated in the delivery room versus intubation with surfactant using two different protocol-driven pre-defined ventilatory strategies. The oxygen saturation component of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of the composite outcome of severe retinopathy of prematurity or death among infants of $24^{0/7}$ to $27^{6/7}$ weeks gestational age at birth. The ventilation part of this factorial design trial, which was used to control the ventilatory approach and test other hypotheses, will be reported separately.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at Research Triangle International, the independent data coordinating center, approved the trial.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Written informed consent was obtained from the parent or guardian of each participant before delivery.

Patients

Infants $24^{0/7}$ to $27^{6/7}$ weeks gestation for which a decision had been made to provide full resuscitation were eligible for enrollment at birth. Outborn infants and those known to have major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of sealed opaque envelopes to oxygen saturation targeting of 85-89% or 91-95% (the lower and higher oxygen saturation target groups, respectively) before birth using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88-92% for the targeted oxygen saturation ranges, with an offset of 3% (Masimo Radical Pulse Oximeter, Irvine, CA). A similar algorithm was used to mask caregivers and separate oxygen saturations in premature infants.[17] Thus, an oxygen saturation display of 88% corresponded to actual oxygen saturations of 85% and 91% in the 85-89% and 91-95% target groups, respectively. Likewise, an oxygen saturation display value of 92% corresponded to actual oxygen saturations of 89% and 95% in the 85-89% and 91-95% target groups, respectively. A display value of 96% corresponded to actual values of 93-96% and 96% in the low and high target groups, respectively. A display

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

value of 84% corresponds to actual values of 87 and 84-87% in the low and high target groups, respectively. The oxygen saturation display transitioned and reverted to actual (non-skewed) values when less than 84% or higher than 96% in both treatment groups. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours, whichever occurred first. Infants who weaned to room air, but who subsequently received oxygen supplementation before 36 weeks post-menstrual age, were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinical, not the research staff. Reports of displayed data by clinical center were provided quarterly to each center for feedback on displayed achieved oxygen targeting performance. For the ventilation part of this 2 x 2 factorial design trial, participants were randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilatory strategy.

Assessments

Research nurses recorded all data using standardized definitions included in the trial Manual of Operations. Data collection, excluding retinopathy of prematurity examinations, was completed at discharge. All surviving infants were followed by ophthalmological specialists familiar with retinopathy of prematurity. Examinations began by 33 weeks postmenstrual age and continued until the study endpoint or resolution was reached. Threshold retinopathy of prematurity (New

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Type 1 threshold per Early Treatment of Retinopathy Cooperative Group[18,19]) was coded if any of the following findings were present:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic intervention was coded if any of the following were present: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, and vitrectomy. Resolution was defined as fully vascularized retinas or immature vessels in zone III for two consecutive examinations in each eye. The primary outcome was death before discharge and/or severe retinopathy defined as threshold retinopathy and/or surgical ophthalmologic surgery and/or bevacizumab treatment for retinopathy. Other outcomes recorded included only predefined clinical diagnoses, including assessment of oxygen need at 36 weeks postmenstrual age[20] and safety outcomes.

Statistical analysis

The analysis for the oxygen saturation part of this factorial trial compared the percent of infants in each treatment arm who developed the primary outcome of severe retinopathy or death. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks and 95% confidence intervals. Continuous outcomes were analyzed using mixed effects linear models to produce adjusted means and standard errors. Survival analysis using Cox regression compared mortality in the low and high oxygen saturation groups. In the analysis of all outcomes, adjustment was performed as pre-specified for stratification by center and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

gestational age as well as for familial clustering due to randomization of multiple births to the same treatment arm. To compare the actual oxygen saturation values in the two treatment arms, a median oxygen saturation value while on oxygen supplementation was determined for each infant. Those values were graphed by treatment group and the medians of the resulting distributions were compared using a Rank Sums test.

An absolute difference of 10% for the composite primary outcome between the two treatment groups was considered clinically important. The sample size calculations were based on the rate of death or threshold retinopathy of 50% in the Neonatal Research Network from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or BPD in the ventilation arm of this factorial trial). Based on an intracluster correlation of 0.12 in this outcome, the sample size was increased by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because this introduced a clustering effect into the design. The required sample size was increased by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to detect, with sufficient power, an interaction effect between the two factorial arms.

Intent-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. To account for multiple testing due to the co-primary outcomes in this factorial trial, a two-sided adjusted p value of less than 0.02 was considered to be statistically significant for the primary outcome of death or severe retinopathy. P values for secondary

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

outcomes are reported descriptively at the per-test level. Analyses of secondary outcomes did not include adjustment for multiple comparisons; however, for the 46 planned secondary outcome comparisons by treatment, we would expect no more than three tests to have a p value of less than 0.05 on the basis of chance alone. Sub-group analyses were conducted within pre-specified gestational age strata on 36 pre-defined outcomes. Although these tests were not adjusted for multiple comparisons, we would expect no more than two tests per stratum to have p values of less than 0.05 based on chance alone.

An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at approximately 25%, 50%, and 75% of planned enrollment. In addition, the Data Safety and Monitoring Committee, upon request of the investigators, evaluated the oxygen saturation data to evaluate compliance with the protocol. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of these events.

RESULTS

1316 infants were enrolled between February 2005 and February 2009 (Figure 1). When 247 infants had been enrolled, enrollment was temporarily paused upon recommendation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Human Development Director because of concerns that displayed oxygen saturations often exceeded the targets Separation of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns because infants not requiring supplemental oxygen accounted for a large proportion of the high saturation levels maintained. Continued enrollment was approved.

The baseline characteristics of the two treatment groups were similar (Table 1). The primary outcome, severe retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28.3 vs 32.1%; RR 0.90; CI 0.76, 1.06; p= 0.20; Table 2). Death before discharge occurred in 130 of the 654 (19.9%) infants in the lower oxygen saturation group versus in 107 of the 662 (16.2%) infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; p= 0.04; number needed to harm 27). The distribution of the major causes of death did not differ significantly between the intervention and control groups (Appendix Table 1). Comparable results were observed for both gestational age strata. Survival analysis using Cox regression produced similar results (hazard ratio 1.32; CI 1.01, 1.72; p= 0.045) (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Severe retinopathy among survivors to discharge, transfer, or one year was decreased in the lower oxygen saturation group (8.6 vs 17.9%; RR 0.52; CI 0.37, 0.73; p< 0.001; number needed to treat 11). Oxygen use at 36 weeks was decreased in the lower oxygen saturation group (p=0.002) but bronchopulmonary dysplasia among survivors determined by the physiological oxygen saturation test at 36 weeks and the composite outcome of bronchopulmonary dysplasia/death by 36 weeks did not differ significantly between the treatment groups. Other pre-specified major outcomes did not differ significantly between the

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

two treatment groups (Table 2). While the trial was not powered to detect an interaction between the oxygen saturation and the ventilatory intervention, we prospectively agreed to evaluate such interactions and none were found.

The median oxygen saturation of infants in the two treatment groups while receiving oxygen supplementation differed substantially but, as expected, there was substantial overlap (Figure 3). These data indicate that actual median oxygen saturation levels were slightly higher than targeted in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Appendix Table 2). Other measures of resource utilization did not differ as well.

DISCUSSION

In this multicenter randomized trial we found that even though lower oxygen saturation targeting reduced severe retinopathy among survivors, it also increased the risk for in-hospital mortality. Longer follow-up will be important to determine the effects on functional visual outcome. Despite the absence of recent randomized trials and safety data and the increase in mortality when a restrictive oxygen supplementation was tested and practiced in the 1950s and 1960s, lower oxygen saturation targeting with the goal of reducing retinopathy of prematurity is becoming common practice.[3-5,15,16,21]

This is the largest randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results, in conjunction with previous reports, add to the concern that oxygen restriction may increase mortality in preterm infants. It is interesting and worrisome that the combined risk difference observed in the trials from the 1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.7% mortality increase in the lower oxygen saturation group that was observed in the current trial.

Randomized trials of oxygen restriction in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17,22] However, these trials aimed for saturations of 91-94% and 89-94% in the lower oxygen saturation group, which are closer to the targets of the higher saturation arm in the current trial. The lower oxygen saturation targets or the use of oxygen restriction from birth in the current trial may be related to the adverse outcome.

Meta-analyses of restriction of oxygen supplementation based on trials from the 1950s to the 1970s showed a large reduction in severe retinopathy (RR 0.19; CI 0.07, 0.50).[1,23] There have not been other randomized controlled trials of different oxygen targeting starting soon after birth. However, like most non-randomized studies[3-5,15,16], our trial confirmed that lower oxygen saturation targeting results in a large reduction of severe retinopathy among survivors.

There are several ongoing trials across the world that address the same intervention tested in the current trial and a planned prospective meta-analysis.[24] These trials use the same algorithm for

oxygen saturation targeting so their data will be combined in a meta-analysis to determine short and long term effects of oxygen saturation targeting.

In summary, oxygen saturation targeting in the 85-89% range did not affect the combined outcome of severe retinopathy/death but it increased mortality while substantially decreasing severe retinopathy among survivors. Neurodevelopmental assessments are being performed at 18-22 months corrected age. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years, but at the present time, caution should be exercised regarding oxygen targeting for premature infants in the low range tested as it may lead to increased mortality.

Subject: VOTE:SUPPORT

For the SUPPORT manuscripts, there are three requests for authorship which have been approved by the SUPPORT Subcommittee:

1. For Alabama, Ambal is requested to be an author based on his pivotal role in the trial at the highest recruiting site.
   ___ yes ___no
2. For Rochester, Dale Phelps is recommended to be added to the oximetry paper due her role in training for ROP and source of ROP advice during the trial.
   ___yes ____no
3. For Cincinnati, Ed Donovan is recommended to be added to the CPAP paper for his role in trial training and serving on the subcommittee until Kurt took over in 2006.
   ___yes ____ no

I am sending this email to the non-SUPPORT subcommittee members for input as the SUPPORT SUBCOMMITTEE has already voted.
Please respond by November 25
Thanks
Rose

Acknowledgements

The National Institutes of Health, the *Eunice Kennedy Shriver* National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD, PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants when exposed to reduced oxygenation levels. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the *Eunice Kennedy Shriver* NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85-89% or 91-95%. The primary outcome was a composite of severe retinopathy of prematurity (threshold, retinopathy, surgical ophthalmologic intervention, or bevacizumab) and/or death before discharge from the hospital.

Results

The rate of severe retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28.3 vs 32.1%; RR 0.90; CI 0.76, 1.06; p= 0.20). Death occurred more frequently in the lower oxygen saturation target group (19.9 vs 16.2%; RR 1.27; CI 1.01, 1.60; p= 0.04) while severe retinopathy among survivors occurred less often in these infants (8.6 vs 17.9%; RR 0.52; CI 0.37, 0.73; p<0.001).

Conclusions

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcome of severe retinopathy/death but resulted in an increase in mortality that and a substantial decrease in severe retinopathy among survivors. The increase in mortality is a major concern as lower saturation targeting is increasingly being advocated to prevent retinopathy of prematurity (clinicaltrials.gov NCT 00233324).

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] This resulted in the practice of restricting oxygen supplementation, which was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6,7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy,[12] and other morbidities. Although a multicenter observational study[13] could not identify an association between PaO_2 levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations between lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3-5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery among very low birth weight infants was higher in infants cared for in neonatal intensive care units that used higher maximum oxygen saturation targets of $\geq$ 92% (3.3 $\pm$ 0.3%) or $\geq$98% (5.6 $\pm$ 1.1%) than in units with lower oxygen saturation targets (1.4 $\pm$ 0.2% and 3.1 $\pm$ 0.3%, respectively).[5] In a retrospective study comparing outcomes at five neonatal intensive care units, the incidence of severe retinopathy requiring ablation therapy was

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

27% in units where target saturations were 88-98% and only 6% in units where the target was 70-90%.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83-95% resulted in a substantial reduction in retinopathy but actual oxygen saturations achieved, mortality, and neurodevelopmental outcomes were not reported.[4,15,16] While data from these recent prospective observational studies, retrospective studies, or controlled studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease the incidence of retinopathy of prematurity, an increase in serious adverse effects or deaths were not reported.

We conducted a 2 x 2 factorial design multicenter randomized controlled trial of two levels of oxygen saturation targeting and continuous positive airway pressure initiated in the delivery room versus intubation with surfactant using two different protocol-driven pre-defined ventilatory strategies. The oxygen saturation component of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of the composite outcome of severe retinopathy of prematurity or death among infants of $24^{0/7}$ to $27^{6/7}$ weeks gestational age at birth. The ventilation part of this factorial design trial, which was used to control the ventilatory approach and test other hypotheses, will be reported separately.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at Research Triangle International, the independent data coordinating center, approved the trial.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Written informed consent was obtained from the parent or guardian of each participant before delivery.

Patients

Infants $24^{0/7}$ to $27^{6/7}$ weeks gestation for which a decision had been made to provide full resuscitation were eligible for enrollment at birth. Outborn infants and those known to have major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of sealed opaque envelopes to oxygen saturation targeting of 85-89% or 91-95% (the lower and higher oxygen saturation target groups, respectively) before birth using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88-92% for the targeted oxygen saturation ranges, with an offset of 3% (Masimo Radical Pulse Oximeter, Irvine, CA). A similar algorithm was used to mask caregivers and separate oxygen saturations in premature infants.[17] Thus, an oxygen saturation display of 88% corresponded to actual oxygen saturations of 85% and 91% in the 85-89% and 91-95% target groups, respectively. Likewise, an oxygen saturation display value of 92% corresponded to actual oxygen saturations of 89% and 95% in the 85-89% and 91-95% target groups, respectively. A display value of 96% corresponded to actual values of 93-96% and 96% in the low and high target groups, respectively. A display

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

value of 84% corresponds to actual values of 87 and 84-87% in the low and high target groups, respectively. The oxygen saturation display transitioned and reverted to actual (non-skewed) values when less than 84% or higher than 96% in both treatment groups. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours, whichever occurred first. Infants who weaned to room air, but who subsequently received oxygen supplementation before 36 weeks post-menstrual age, were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinical, not the research staff. Reports of displayed data by clinical center were provided quarterly to each center for feedback on displayed achieved oxygen targeting performance. For the ventilation part of this 2 x 2 factorial design trial, participants were randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilatory strategy.

Assessments

Research nurses recorded all data using standardized definitions included in the trial Manual of Operations. Data collection, excluding retinopathy of prematurity examinations, was completed at discharge. All surviving infants were followed by ophthalmological specialists familiar with retinopathy of prematurity. Examinations began by 33 weeks postmenstrual age and continued until the study endpoint or resolution was reached. Threshold retinopathy of prematurity (New

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Type 1 threshold per Early Treatment of Retinopathy Cooperative Group[18,19]) was coded if any of the following findings were present:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic intervention was coded if any of the following were present: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, and vitrectomy. Resolution was defined as fully vascularized retinas or immature vessels in zone III for two consecutive examinations in each eye. The primary outcome was death before discharge and/or severe retinopathy defined as threshold retinopathy and/or surgical ophthalmologic surgery and/or bevacizumab treatment for retinopathy. Other outcomes recorded included only predefined clinical diagnoses, including assessment of oxygen need at 36 weeks postmenstrual age[20] and safety outcomes.

Statistical analysis

The analysis for the oxygen saturation part of this factorial trial compared the percent of infants in each treatment arm who developed the primary outcome of severe retinopathy or death. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks and 95% confidence intervals. Continuous outcomes were analyzed using mixed effects linear models to produce adjusted means and standard errors. Survival analysis using Cox regression compared mortality in the low and high oxygen saturation groups. In the analysis of all outcomes, adjustment was performed as pre-specified for stratification by center and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

gestational age as well as for familial clustering due to randomization of multiple births to the same treatment arm. To compare the actual oxygen saturation values in the two treatment arms, a median oxygen saturation value while on oxygen supplementation was determined for each infant. Those values were graphed by treatment group and the medians of the resulting distributions were compared using a Rank Sums test.

An absolute difference of 10% for the composite primary outcome between the two treatment groups was considered clinically important. The sample size calculations were based on the rate of death or threshold retinopathy of 50% in the Neonatal Research Network from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or BPD in the ventilation arm of this factorial trial). Based on an intracluster correlation of 0.12 in this outcome, the sample size was increased by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because this introduced a clustering effect into the design. The required sample size was increased by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to detect, with sufficient power, an interaction effect between the two factorial arms.

Intent-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. To account for multiple testing due to the co-primary outcomes in this factorial trial, a two-sided adjusted p value of less than 0.02 was considered to be statistically significant for the primary outcome of death or severe retinopathy. P values for secondary

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

outcomes are reported descriptively at the per-test level. Analyses of secondary outcomes did not include adjustment for multiple comparisons; however, for the 46 planned secondary outcome comparisons by treatment, we would expect no more than three tests to have a p value of less than 0.05 on the basis of chance alone. Sub-group analyses were conducted within pre-specified gestational age strata on 36 pre-defined outcomes. Although these tests were not adjusted for multiple comparisons, we would expect no more than two tests per stratum to have p values of less than 0.05 based on chance alone.

An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at approximately 25%, 50%, and 75% of planned enrollment. In addition, the Data Safety and Monitoring Committee, upon request of the investigators, evaluated the oxygen saturation data to evaluate compliance with the protocol. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of these events.

RESULTS

1316 infants were enrolled between February 2005 and February 2009 (Figure 1). When 247 infants had been enrolled, enrollment was temporarily paused upon recommendation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Human Development Director because of concerns that displayed oxygen saturations often exceeded the targets Separation of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns because infants not requiring supplemental oxygen accounted for a large proportion of the high saturation levels maintained. Continued enrollment was approved.

The baseline characteristics of the two treatment groups were similar (Table 1). The primary outcome, severe retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28.3 vs 32.1%; RR 0.90; CI 0.76, 1.06; p= 0.20; Table 2). Death before discharge occurred in 130 of the 654 (19.9%) infants in the lower oxygen saturation group versus in 107 of the 662 (16.2%) infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; p= 0.04; number needed to harm 27). The distribution of the major causes of death did not differ significantly between the intervention and control groups (Appendix Table 1). Comparable results were observed for both gestational age strata. Survival analysis using Cox regression produced similar results (hazard ratio 1.32; CI 1.01, 1.72; p= 0.045) (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Severe retinopathy among survivors to discharge, transfer, or one year was decreased in the lower oxygen saturation group (8.6 vs 17.9%; RR 0.52; CI 0.37, 0.73; p< 0.001; number needed to treat 11). Oxygen use at 36 weeks was decreased in the lower oxygen saturation group (p=0.002) but bronchopulmonary dysplasia among survivors determined by the physiological oxygen saturation test at 36 weeks and the composite outcome of bronchopulmonary dysplasia/death by 36 weeks did not differ significantly between the treatment groups. Other pre-specified major outcomes did not differ significantly between the

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

two treatment groups (Table 2). While the trial was not powered to detect an interaction between the oxygen saturation and the ventilatory intervention, we prospectively agreed to evaluate such interactions and none were found.

The median oxygen saturation of infants in the two treatment groups while receiving oxygen supplementation differed substantially but, as expected, there was substantial overlap (Figure 3). These data indicate that actual median oxygen saturation levels were slightly higher than targeted in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Appendix Table 2). Other measures of resource utilization did not differ as well.

DISCUSSION

In this multicenter randomized trial we found that even though lower oxygen saturation targeting reduced severe retinopathy among survivors, it also increased the risk for in-hospital mortality. Longer follow-up will be important to determine the effects on functional visual outcome. Despite the absence of recent randomized trials and safety data and the increase in mortality when a restrictive oxygen supplementation was tested and practiced in the 1950s and 1960s, lower oxygen saturation targeting with the goal of reducing retinopathy of prematurity is becoming common practice.[3-5,15,16,21]

This is the largest randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results, in conjunction with previous reports, add to the concern that oxygen restriction may increase mortality in preterm infants. It is interesting and worrisome that the combined risk difference observed in the trials from the 1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.7% mortality increase in the lower oxygen saturation group that was observed in the current trial.

Randomized trials of oxygen restriction in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17,22] However, these trials aimed for saturations of 91-94% and 89-94% in the lower oxygen saturation group, which are closer to the targets of the higher saturation arm in the current trial. The lower oxygen saturation targets or the use of oxygen restriction from birth in the current trial may be related to the adverse outcome.

Meta-analyses of restriction of oxygen supplementation based on trials from the 1950s to the 1970s showed a large reduction in severe retinopathy (RR 0.19; CI 0.07, 0.50).[1,23] There have not been other randomized controlled trials of different oxygen targeting starting soon after birth. However, like most non-randomized studies[3-5,15,16], our trial confirmed that lower oxygen saturation targeting results in a large reduction of severe retinopathy among survivors.

There are several ongoing trials across the world that address the same intervention tested in the current trial and a planned prospective meta-analysis.[24] These trials use the same algorithm for

oxygen saturation targeting so their data will be combined in a meta-analysis to determine short and long term effects of oxygen saturation targeting.

In summary, oxygen saturation targeting in the 85-89% range did not affect the combined outcome of severe retinopathy/death but it increased mortality while substantially decreasing severe retinopathy among survivors. Neurodevelopmental assessments are being performed at 18-22 months corrected age. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years, but at the present time, caution should be exercised regarding oxygen targeting for premature infants in the low range tested as it may lead to increased mortality.

Table 1. Baseline Characteristics of the Patients in a Randomized Trial of Lower versus Higher Oxygen Saturation Targets in Extremely Low Birth Weight Infants

Characteristic	Lower Saturation Group (N = 654)	Higher Saturation Group (N = 662)
Birthweight – g (m±SD)	836±193	825±193
Gestational age – wk (m±SD)	26±1	26±1
Male sex – no. (%)	341/654 (52.1)	371/662 (56.0)
Race or ethnic group – no. (%)		
White (non-Hispanic)	242/654 (37.0)	279/662 (42.1)
Black (non-Hispanic)	257/654 (39.3)	232/662 (35.0)
Hispanic	132/654 (20.2)	127/662 (19.2)
Other/unknown	23/654 (3.5)	24/662 (3.6)
Antenatal corticosteroids (any) – no. (%)	633/654 (96.8)	632/661 (95.6)
Antenatal corticosteroids (full course) – no. (%)	477/651 (73.3)	462/658 (70.2)
5-min Apgar score < 3 – no. (%)	34/654 (5.2)	24/662 (3.6)
Surfactant – no. (%)	531/653 (81.2)	558/660 (84.5)

How did they know whether the baby had majority saturation >=90% based on the altered oximeters? An actual saturation of 90% would have corresponded to a display value of 87 or 93 depending on whether the low or high oximeter was used.

It was decided based on their status at 36 weeks--they were on the Massimos at that time. However, as part of the physiologic reduction, all babies were put on a unit (nonblinded, nonskewed) oximeter for a baseline period, then reduced if continuing to meet the criteria for reduction. There should have been no difference in failure rate in the babies who were in the high sat group vs. the low sat group.

Monica and Shirley:

Did we decide on the need for physiologic test based on the study oximeter or the regular one?

Subject: RE: Support information.

Are we all clear about this? The study oximeter was in place on the 36 week date (we removed it the next day). Whether or not an infant is reduced using the Physiologic Definition is determine by the effective oxygen on that 36 week day. We had a week after the 36 week date to perform the physiologic definition.

Dr. Tyson, I believe that Dr. Kennedy's assessment is correct. All the centers should have done it the same way. The Masimo oximeter stayed on the infant through the 36 week date and BPD criteria is on the 36 week date. The reduction is to be done within 1 week of the 36+1 week date. 1. Oxygen by NC <27% effective oxygen and the majority of saturations greater than or equal to 90% in the prior 24 hours is eligible for reduction. 2. Oxygen by NC 27-30% effective oxygen and the majority of saturations greater than or equal to 96% in the prior 2 hours are eligible for reduction. 3. Room air NC at any liter flow is eligible for reduction. The Masimo oximeters displayed a target of 88-92% on both the high and low range altered oximeters. Low range was actual 85-89% target and the high range was actual 91-95% target. Since the study monitor was removed from the infant on the 36+1 date the reductions were done on the unit monitors and this should be consistent with all the centers. I have the MOP in the office of both the Support and BPD if you need them. I hope that this helps.

Subject: Re: Support information.

As I understand it, they used a non-study sat momitor for the oxygen challenge so that was done the same way in both groups. The difference between the O2 sat groups was that the criteria for deciding who qualified for the challenge were based on the amount of O2 needed to achieve the study targets. Presumably babies in the high sat group would be more likely to get a challenge, and therefore slightly more likely to fail, than babies in the low sat group.

Kathleen, In the MOP on page 16-1 it states that the information is collected through 36 weeks and on page C-1 we used the BPD MOP for the reduction. We took the Masimo off the patients the day after their 36 week date then according to the BPD MOP we did the reduction if they qualified within 1 week. Therefore the information to determine if the patient qualified for the reduction was from the Masimo on the 36 week date and the reduction was done using the saturations from the unit monitors within a week. Please let me know if you have any further questions. Patti

Rose
I generally stay away from any discussion about authors, but I have a concern as to why there are 3 authors for Cincinnati.
Is there a reason?
I believe that I have had input from Kurt. In any case I do not support 3 PIs from one center unless they were the lead unit (Wally was) or there was some other mitigating situation. Many of the main PIs are not on the author list.
Can we change this??
Thanks
Neil

ABSTRACT

Background

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The purpose of this study was to quantify the time, effort, and rate of success involved obtaining antenatal consent to enroll infants into the Neonatal Research Network SUPPORT trial, and to determine if these infants were representative of the eligible population.

Methods

Eligible subjects were those likely to deliver in the SUPPORT gestational age window (24-27 6/7 wks). Data included who approached them for consent, how often they were approached, the duration of each contact, whether consent was obtained and if the infant(s) was enrolled in the trial. In addition, all eligible, non-enrolled infants entered into the NRN Generic Database (GDB) throughout the period of SUPPORT enrollment were identified to allow comparison of all infants enrolled in SUPPORT to those who were eligible but not enrolled.

Results

2826 women were identified at 18 sites between October 2005 and February 2009. 2228 were approached for consent and 1219 (54.7%) agreed. For 76.9% of those approached, < 3 visits were required to complete the consent process. (mean 2.0 +/- 1.2). Of the 659 consented infants delivered within the study window, 611 of were enrolled. Mothers who received a neonatal consult were more likely to give consent ($p<.001$). Comparing all GDB infants who were eligible for SUPPORT but whose mothers were not approached (n=2290) to those whose mothers were approached (n=2082), the percentage of infants not exposed to steroids was significantly greater in the non-approached vs. the approached group (20.0%, 3.4% $p<.001$).

Conclusions:

In a trial of preterm infants requiring antenatal consent, more than 5 women were identified as likely to deliver in the GA window for each one who delivered an enrolled infant. The differences between enrolled and non-enrolled infants highlight difficulties in attempting to recruit a representative population for trials requiring antenatal consent.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Introduction:

Informed consent ensures that subjects enrolled in research trials are appropriately informed as to the risks and benefits of the trial, came to the trial voluntarily. Traditionally, this consent is obtained directly from the subject when they are in condition to understand and participate in the process. In conducting trials on infants who will receive an intervention at or near the time of birth, the process requires approaching families prior to delivery.

Funding for clinical trials sponsored by federal agencies and industry is often based on a model of capitation in which a site is paid based on the number of subjects enrolled. Funds may be awarded for screening for eligible subjects, but centers are not usually paid for the time required to seek or obtain consent for subjects who are not enrolled. However, because prospective data comparing the number of families who are approached in the antenatal period to the number of infants who are actually enrolled have not previously been available, the current model may not adequately account for time spent by study staff to screen, approach and enroll all eligible subjects.

The early months of enrollment in the Surfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants (SUPPORT) demonstrated that antenatal screening and consent were labor intensive and that the number of patients enrolled seemed to be much lower than the number screened. Thus, this secondary study was designed to quantify the antenatal screening and consent process to determine the time, effort and other factors that contribute to successful enrollment of patients in a complex trial conducted by an experienced multi-center trials network. The second objective of the study was to determine whether the subjects enrolled in the trial were representative of the overall eligible population.

Methods:

This is a prospective cohort study of the antenatal consenting practices of research personnel in the multi-center Neonatal Research Network (NRN) funded by the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD). Data for this study were collected during the

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

second half of the NRN SUPPORT trial. The SUPPORT trial was designed to compare the use of early Continuous Positive Airway Pressure (CPAP) initiated in the delivery room to early intubation and surfactant given within the first hour of life, in a 2x2 factorial design with randomization to two different target SpO2 ranges during receipt of supplemental oxygen up to 36 weeks post menstrual age (PMA). Eligible infants were those inborn at NRN centers at 24 0/7ths to 27 6/7ths weeks gestational age (GA) without known malformation for whom full postnatal treatment was planned. SUPPORT enrollment began in February 2005 and ended in February 2009.

Eligible subjects for the antenatal consent secondary study were those women whom the Obstetrical/Perinatal staff thought were likely to deliver in the SUPPORT gestational age window. Clinical data were collected by trained research coordinators, and all analyses were performed at a central data coordinating center (RTI International, Research Triangle Park, NC). Research staff collected study data using a one page data collection form. If the parent(s) were not approached for consent, the reason they were not approached was recorded. If they were approached, the staff recorded the total number of times the parent(s) were approached, the number of such attempts that were made by the research coordinator/RN, and whether permission from the obstetrician was obtained to approach for antenatal consent. Because a neonatal consult is often performed as part of clinical management in this population, staff recorded whether a consult was performed, whether the consent was discussed during the consultation, and whether consent was obtained at the time of the consult. In some centers the Institutional Review Board required a consult be completed prior to consent, so this was also recorded. Women who were approached were asked if they were asked to participate in any other studies for themselves or their infants. Finally, the study staff was asked to estimate the time required to obtain a decision regarding consent.

Data were collected at each of the 18 NICHD NRN centers until fifty mothers had delivered within the window at the center. Data forms were keyed by the centers and transmitted electronically to the Data Coordinating Center. As part of the ongoing NRN Generic Database (GDB) observational

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

study, data were routinely collected on inborn infants at NRN centers, including most of those who met the gestational age eligibility criteria for the SUPPORT study. These data were used to identify eligible non-enrolled (non-consented) infants and to evaluate whether infants enrolled in the SUPPORT trial represented the eligible NRN population.

To determine the representativeness of the population enrolled in the SUPPORT trial, data from the GDB were obtained for those infants born at NRN centers during the period of SUPPORT trial enrollment met enrollment criteria for participation in SUPPORT. Eligible but non-enrolled infants had information collected on prenatal care, the use of antenatal steroids and demographic data. These data were compared for infants who were or were not enrolled in SUPPORT to assess whether the trial had enrolled a representative sample of the available population. In addition, comparisons were made between eligible infants whose mothers were or were not approached for SUPPORT. These data were used to determine whether all eligible women were approached and if not, what the reasons for not approaching them were.

We performed bivariate statistical analyses using Chi-Square and Student's t-tests. All statistical analyses were performed using SAS version 9.1.3 (SAS Institute Inc., Cary, NC). A p value of less than 0.05 was considered statistically significant. This trial was approved by the Institutional Review Boards of all participating centers as well as that of RTI.

Results

Between October 2005 and February 2009, a total of 2826 women were identified at 18 NRN centers as being at risk for delivering a premature infant between 24 to 27 6/7 wks GA and otherwise eligible for participation in the SUPPORT trial. Two NRN centers did not participate in the antenatal consent trial and 4 participating centers did not identify 50 eligible women who delivered in the GA window between the start of data collection for the antenatal consent study and the end of the SUPPORT trial. Thirteen centers had more than 50 women deliver in the GA window (range 51 to 90) before they stopped collecting data. All data collected by participating centers have been included in this analysis. Analysis

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

using only the first 50 women from the centers that over-enrolled was not significantly different. Screening, enrollment and consent numbers by center are presented in Figure 1.

2228 women were approached for informed consent. The two most frequent reasons for not attempting to obtain consent were early discharge and a lack of time prior to delivery (Table 2). Common choices within the "other" category in the table were the inability of the mother to give consent, fetal abnormalities, and language barriers that made informed consent impossible. Mothers were considered unable to give consent when in active labor, too young, or having either a mental or physical health issue which precluded them being approached.

A study coordinator or research RN made 74.7% of all approaches. For 76.9% of those women approached, consent was attempted < 3 times. (Overall mean 2.0 +/- 1.2). The frequency of approaches ranged from 1 (n=900) to 11 (n=2) times. The median time spent to obtain a decision regarding consent was less than 1 hour regardless of the decision. The estimated GA at time of screening was not significantly different for those who consented versus those who did not. Of the 2228 mothers approached, 1219 (54.7%) gave consent, and 581 subsequently delivered within the SUPPORT study window. Of these, 536 delivered infants who were enrolled (Figure 2). Forty-eight of the 659 consented infants born in the GA window (7.3%) were not enrolled, usually due to lack of staffing, equipment, or time. Only 19% of those mothers screened delivered infants who were subsequently enrolled in the study. A neonatal consult was performed in 69.7% of cases where the parent(s) were approached for consent. Mothers receiving a neonatal consult were more likely to consent ($p < .001$), but consent was obtained during the consult in only 11.6%.

Comparing all GDB infants who were eligible for SUPPORT but whose mothers were not approached to those whose mothers were approached revealed several important differences (Table 2). Infants of approached mothers were significantly more likely to be non-Hispanic white; to be older, and to have a high school education , private medical insurance, and at least one PNC visit. A significantly higher proportion of eligible infants whose mothers were not approached had no exposure to antenatal

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

steroids compared with infants whose mothers were approached (20.0% vs 3.4%, p<.001). Maternal parity was lower in women who were approached, but gravidity was not significantly different between the groups.

Eligible GDB infants who were not enrolled in SUPPORT and those who were enrolled were also significantly different. Non-enrolled infants had mothers who were significantly less likely to have insurance and to have received prenatal care and were over 4 times more likely to have gone without antenatal steroids (15.7% vs. 3.8%) (Table 3).

Discussion:

To our knowledge this is the first study to evaluate the time and efforts required to approach and obtain antenatal consent from parents for the enrollment of their unborn infants. Our results reveal that 5 families needed to be identified and screened for every one infant successfully enrolled. Only 47.7% of women consented went on to deliver infants in the study window. Though the time needed to obtain consent was collected as a discrete variable, we found that the median was between 30 minutes and 1 hour. Multiplying these bounds by the number of women approached for each enrolled infant (3.6) yields a value for coordinator time required to obtain an enrolled infant at between 1.8 and 3.6 hours. Assuming that the enrollment rate of the SUPPORT trial was equivalent before data collection for the antenatal consent study began suggests that over 2400 hours were spent screening greater than 6000 women and approaching nearly 4800 for consent to enroll 1316 infants in the SUPPORT trial. This estimate includes time spent approaching women who did not consent and consenting women who did not deliver in the window. It does not account for time spent screening women who were not approached for consent.

Morley et al reviewed parental willingness to participate in multiple trials in the neonatal period and found that most (74%) were willing to allow their baby to participate in multiple trials. [1] We had concerns that the burden of being approached for multiple trials, especially since 5 centers also belonged to a maternal/fetal research network, would affect the enrollment in SUPPORT. We found

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

that only 8.4% of women reported having been approached for another trial at the time of the SUPPORT consent discussion, probably because it was an antenatal consent and the window was early in gestation.

Because of the unique attributes of the NRN, we were able to obtain demographic data from the GDB for infants who were delivered in the SUPPORT gestational age window but were not enrolled in the study. Thus, we were able to compare infants who were vs. were not enrolled and those whose mothers were vs. were not approached. The approached vs. non-approached data help us to better understand what part of the population never had an opportunity to be part of the enrollment, and what the reasons were. The enrollment data allow us to compare the population that was enrolled in the trial with those who were eligible but not enrolled. This is the ultimate result of the consent process.

Infants born to women who were not approached for consent were almost 6 times more likely not to have been exposed to antenatal steroids, an intervention known to be associated with better short and longer term outcomes for preterm infants.[1,2] They were also more likely to be more immature and their mothers were significantly less likely to have insurance and to have received prenatal care.

Comment [h1]: The 2 does not refer to the consent, but rather to the steroids themselsve. Recommendation to split this sentence into 2 sentences.

In a review of NIH funded interventional randomized controlled trials, Charlson and Horwitz found that only half such trials kept any data on subjects who were eligible but not enrolled, and for those trials which collected data only 27% of eligible non-enrolled subjects were a result of subject refusal.[3] The Consolidated Standards for Reporting of Trials (CONSORT) is a document created with the intent of standardizing items reported in trial publications, including a checklist for necessary items.[4,5] The standards require a flow chart of participants to quantify eligible populations but it does not require identifying the demographics of the non-enrolled group or its similarity to the enrolled or consented populations. Following the CONSORT standards in all antenatal consent trials, that is, obtaining basic demographic information for all eligible infants, will help us understand whether similar reduction biases in enrollment occurs in other studies.

Blinding of allocation has always been the benchmark for protecting trials from biased enrollment. Investigators have shown that trials in which allocation to a study group is well concealed more accurately reflect the true study effect than those not well concealed.[6] However, these controls only protect the trial from internal bias, not the selection bias we have seen. It does not affect the external validity or generalizability of the findings to non-study patients. Manning and Silverman have voiced concerns about this type of selection bias, stating that a disproportionate number of vulnerable and deprived families are involved in clinical research.[7,8] Harth and Thong questioned parents who had volunteered in an asthma trial in Australia and concluded that volunteering parents were "significantly more socially disadvantaged and emotionally vulnerable." [9] In a study of recruitment and retention of premature infants into an early intervention trial, Constantine et al found significant enrollment bias in this direction related to race, weight and site. [10,11] In our study, the sociodemographic variables tended to favor the enrolled group. Mitchell and Kline showed a significantly greater proportion of African-Americans, uninsured patients, and Medicaid recipients in the non-participant group in a minimal risk emergency department study.[12] Aagaard-Tillery and the NICHD Maternal Fetal Medicine (MFM) network found that blacks and Hispanics were significantly less likely to allow use of their genetic samples for future studies.[13] In our study, the socio-demographic variables tended to favor the enrolled group.

Our analysis would suggest that under-privileged subjects were less likely to participate. Because this trial included subjects from 18 academic centers with long-term experience in randomized trials and a broad mix of racial, ethnic, and socio-economic populations, it is not likely that the bias represents an intention to include or exclude any group. The logical conclusion is that the many subjects who were not enrolled in this trial, despite the significant time and effort spent by the coordinators to include them, represent a failure of, or an innate problem with, the antenatal-consent process itself. Our observations, along with previous experience in a trial of a delivery room intervention[14], suggest that it may be ethically appropriate to allow trials that compare routinely used interventions to waive

Comment [h2]: You may wish to use more exact terms such as self pay/uninsured. Also, those who were approached were more likely to have a high school education than those not approach!!

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

the consent process until after birth. This would ensure that the infants enrolled in such a trial do not differ significantly from the overall eligible population and insure the generalizability of the results.

Conclusion

Our prospective analysis of the process of antenatal consent enrollment in the NICHD Neonatal Research Network SUPPORT trial has shown that antenatal screening and consent are labor intensive, that actual patient enrollment numbers may be significantly lower than screening and consent rates, and that the population enrolled as a result of antenatal consent may not be representative of the total eligible population. In this complex interventional trial of preterm infants, nearly 5 women were identified as likely to deliver a baby in the window for every infant enrolled in the trial. Antenatal steroid use was significantly higher among infants enrolled in the SUPPORT study compared to those who were eligible but not enrolled, with a similar difference between infants born to approached and non-approached women. Along with quantifying the time and expense of antenatal consent, these observations point out the difficulties in attempting to recruit a representative population for prospective trials requiring antenatal consent and suggest that greater use of waiver of consent for trials that are low risk may be appropriate for future studies.

Subject: SUPPORT AUTHORSHIP

Hi
A request is being made to include a second author, Ambal, from University of Alabama on both SUPPORT papers. As you are probably aware, Alabama was the highest recruiter in the trial with 184 of the 1316 infants enrolled. Ambal took charge of SUPPORT recruitment when Wally was not available and was instrumental in the performance at the Alabama site.

Please send me a yes/no vote to include Ambal by 11/25

Thanks
Rose

Date:	Tuesday, November 24, 2009 9:14:00 AM
Attachments:	Evans comprehensive proposal for protocol review committee1 (2).docx Summary review 24Nov0909.doc

Hi
Attached is the comprehensive care proposal and yesterday's Protocol review summary (This will be posted on the RTI private site) for discussion.

Recent vote results:
Allow Matt Laughon and Ron Goldberg to use NRN GDB and Benchmarking abstract information in a CHOICE grant – approved 13 yes votes.

NRN Authorship on papers (author order by site) – We will leave the current policy in place – votes were:
Leave "as is" – 10
Change to absolute number recruited – 5
New combination – 3 with proposals for:

- 75% credit for absolute numbers and 25% for enrolled/eligible
- 33% for absolute #, 33% for % enrolled of screened and 33% of % enrolled of eligible
- Two tiers, with centers whose total enrollment is below some threshold going to the second tier. The threshold might be based on the fraction of total enrolled such as N/no of centers participating. IE for support 1300/20=65

For the SUPPORT manuscripts, there are three requests for authorship which have been approved by the SUPPORT Subcommittee:

1. For Alabama, Ambal is requested to be an author based on his pivotal role in the trial at the highest recruiting site.
2. For Rochester, Dale Phelps is recommended to be added to the oximetry paper due her role in training for ROP and source of ROP advice during the trial.
3. For Cincinnati, Ed Donovan is recommended to be added to the CPAP paper for his role in trial training and serving on the subcommittee until Kurt took over in 2006.

I will send a vote to the SC members for the above three items.

Thanks
Rose

Purpose, Scope, & Anticipated Contribution. We propose a multicenter, comparative effectiveness trial among high risk infants discharged from a neonatal ICU to demonstrate that their incidence of serious illness—illness resulting in death, admission to a pediatric ICU (**PICU**), or prolonged hospital stay—is lower with comprehensive then conventional follow-up (**FU**) care. We previously conducted a large single-center randomized trial funded by the Agency for Health Care Policy and Research and published in JAMA[1]) which showed that comprehensive FU care substantially reduced life threatening illness (death or PICU admission) without increasing health care costs. While these findings have not been questioned, few centers provide such care. The study we now propose is to address the obstacles, establish comprehensive care, and verify the benefits in multiple centers of the NICHD Neonatal Research Network (**NRN**). This study clearly fits the NRN mission to conduct clinical trials and outcomes research to augment the short & long term outcomes of high risk infants. It also fits well with multiple priorities for comparative effectiveness research that have published by the Agency for Health Care Quality and Research and the Institute of Medicine, particularly research: "to compare the effectiveness of... comprehensive support services for infants and their families following discharge from a neonatal intensive care unit." If the proposed research is successful, it would establish a new model of care for neonatal FU programs.

Acceleration of Scientific Research & Creation and Retention of Jobs. Operating under a competitive cooperative agreement, the NRN has been a quite successful in conducting comparative effectiveness studies to advance neonatal care. However, it has not yet undertaken a trial of FU care, and all NRN research funds for the coming 2-3 years have been committed. As described below, the proposed study would advance NRN research by addressing an important neglected topic in pediatrics--the care of high risk infants after discharge home. The study would also promote a neglected kind of pediatric research--T3 translational research, which is designed to successfully provide effective methods of care in different settings.[2,3,4] The study will help stimulate the economy by retaining/hiring clinic staff, research nurses, & nurse practitioners in multiple centers. If successful, it will also promote the long term goal of increasing health care access and effectiveness while controlling costs.

Rationale for Comprehensive FU Care. FU clinics—in marked contrast to neonatal ICUs—have changed little in the past 50 years. Yet, there has been a dramatic increase in the number of high risk infants who survive to be discharged home with a complex mix of ongoing problems, including chronic lung disease, neurologic, gastrointestinal, nutritional, and other problems. Few practicing pediatricians can commit the time or have the experience to develop and maintain skills in treating the acute and chronic illnesses and complications common among these infants. Caregivers with special availability, experience, and commitment are needed during the transition between NICU discharge and one year of age when these infants' problems are more readily treated by pediatricians in the community.

Evidence for Comprehensive Care. The trial noted above included 887 very low birth weight, ventilator treated infants discharged from Parkland Memorial Hospital (Dallas, TX) and randomly assigned to either a) conventional FU care (which in that center included care for chronic illnesses and usual well baby care) or b) comprehensive FU care (which *also* included care for acute illnesses from pediatrician-supervised practitioners and 24-hr access to the primary caregiver in the clinic or by phone). The infants were treated at Children's Medical Center, the private hospital adjacent to Parkland. Faculty supervised residents in the clinics and emergency rooms treated acute illnesses among conventional care infants. The primary outcome was life-threatening illness (illness resulting in death or PICU admission) before 1 year. Comprehensive care resulted in:

- 47% fewer infants with life-threatening illness (33 vs. 62; p=0.001).
- Comparable known deaths (11 vs. 13; p=0.68) but fewer infants who were not known to be alive at 1 year adjusted age despite yearly searches of local clinic and hospital records or Texas Medicaid records (9 vs. 28; p=0.001)
- 57% fewer PICU admissions (23 vs. 53, p=0.003)
- 42% fewer intensive care days (254 vs. 440, p=0.003)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

- 18% fewer emergency department (**ED**) visits (597 vs. 730; p <0.03)
- A mean increase of only 3.1 FU clinic visits and 6.7 phone calls per infant.
- No increase in mean total health care costs per infant to one year: $6265 for comprehensive care vs. $9913 for conventional care (p>0.05) (independently assessed from a societal perspective by health care economists at the U.T Houston School of Public Health using department-specific cost to charge ratios).
- No reduction in the hospital's financial "bottom line" (mean of reimbursements minus costs per infant = $1070 loss with comprehensive care vs. $2977 loss with conventional care.)

Though not formally assessed, costs to the Medical School were undoubtedly lower with comprehensive than conventional FU care due to the lower salaries for faculty in the clinic than in the PICU and lower total faculty hours devoted to treating these infants. Parental expenses and inconvenience were also clearly reduced. .

Thus, the findings of this large trial indicate that comprehensive FU care can have major benefits for high risk infants without increasing costs from a societal, hospital, medical school, or parental perspective.

Generalizability to other locales. The benefits of comprehensive care might be less in some places where the parents of high risk infants are better educated or their community pediatricians are unusually available and skilled in treating such infants. However, the Dallas trial may well provide a conservative estimate of the potential incremental benefits over conventional FU care in most locales because: a) conventional FU care in Dallas—in contrast to that in most centers--included care for chronic illnesses (a factor likely to have reduced the observed incremental benefit of comprehensive care); b) insurance coverage did not affect access to conventional FU care in the Dallas trial. In many locales access to private practitioners is limited for uninsured high risk infants. Even for those who are insured, access may be limited by inadequate reimbursement for all the time required to treat complex conditions or by the reluctance of the physician to see patients that he/she does not feel well trained to treat; c) immediate access to hospital facilities for infants presenting with life-threatening illnesses or complication is not available in the office of most private practitioners as it was for infants given conventional FU care in Dallas and in hospital-based FU clinics in other locales.

Ready access to care-givers with special availability, experience, and commitment has been found to be beneficial across a broad variety of high risk populations In the trial above, the number needed to treat (**NNT**) with comprehensive care to prevent one child with life-threatening illness was only 13. Even if the NNT were twice this value in other locales, it would still be an extraordinarily low for such an important benefit.

Need for a T3 Comparative Effectiveness Trial. Neither the results of the Dallas Trial nor the potential value of comprehensive FU care in other locales has been questioned by neonatologists or FU clinic directors. Yet, we know of only two U.S. cities where such care is available: Dallas, where the trial findings convinced the administration of Children's Medical Center, Parkland Memorial Hospital, and UT Southwestern to jointly fund the program (directed by Dr. Heyne), and Houston, where the Chairman of Pediatrics agreed to fund a program (recently started by Drs. Evans & Tyson).

The paucity of comprehensive care programs presumably reflects the current funding of medical care (with little financial incentive to reduce hospital admissions by improved outpatient care), the traditional goal and staffing of FU clinics (to assess neurodevelopmental outcome), and the need to tailor comprehensive care programs to the local setting. Such issues may be best addressed through T3 translational research, research to assess how to most successfully provide effective methods of care in different practice settings.[2,3,4] Such research often follows T2 research, such as the Dallas Phase III trial described above, that demonstrates the clinical effectiveness of health care interventions. (T2 research generally builds on T1 research, e.g., preclinical or Phase II/II trials) to develop efficacious interventions,).

We propose a T3 comparative effectiveness study in which each intervention center will initiate a comprehensive care program, develop methods to progressively increase its efficiency and effectiveness within the local setting. In an environment in which health care funding is increasingly geared to improve outcomes and control costs, such results from a high profile study would help promote adequate reimbursement and wide

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

use of comprehensive FU care. With an already well established FU mechanism, the NRN is best positioned to conduct such a study most effectively and with lowest research costs.

Study Design & Hypotheses. Designs other than randomized trials may well be needed for comparative effectiveness research, particularly T3 studies.[5] We will assess outcome changes in successive infant cohorts as intervention centers introduce and refine comprehensive care in their particular setting. The cohorts will be based on date of discharge home, and the outcomes of each cohort will be assessed through one year postnatal age. During the 3 year study, we will assess infants discharged from intervention centers during two successive 6-month pre-intervention control periods and three 6-month intervention periods in intervention centers. (The inclusion of two 6-month control periods will allow each intervention cohort to be compared to a cohort discharged one year earlier and will facilitate adjustment for season in the analyses.) We will also assess infant cohorts born during the same time periods in comparison centers that do not provide comprehensive care.

Study population: Intervention centers can choose provide comprehensive care to not only infants born at <26 completed weeks, a group that is assessed as part of Network follow-up program, but also other predefined high risk groups of infants (e.g., all infants <29 weeks gestation). The target population will be limited to infants living within specified geographic boundaries to exclude infants for whom comprehensive follow-up care could not be reasonably provided by center staff. Comparison centers are not expected to assess infants who would not be evaluated in the Network follow-up program. (The differences in population of intervention and comparison centers will be addressed as described below in the hypotheses and analyses sections.) Seven or eight NRN centers will be selected to serve as intervention centers, based on their capacity and commitment to meet the requirements for comprehensive care described below. UT-Houston which only recently began implementing comprehensive care will be considered an intervention site; UT-Southwestern in Dallas has a well established comprehensive primary care program and will not be included as either intervention or comparison center.

Primary hypotheses: **1. In analyses controlling for center, serious illness--death, PICU admission, or prolonged hospital stay (>80th percentile for all study infants) between discharge from a neonatal ICU and before 12 months after birth--will be progressively reduced among successive cohorts of eligible high risk infants in the intervention centers; 2. The reduction in serious illness between discharge from a neonatal ICU and one year age among infants followed in all NRN centers (infants ≤26 weeks gestational age) will be greater in intervention centers than in comparison centers that do not implement such care.**

The primary outcome includes a prolonged hospital stay (which was not included in the primary outcome in the Dallas trial) to afford greater statistical power and to capture additional expensive and medically important hospitalizations that would not be identified by PICU admissions only.

Secondary hypotheses (addressing secondary outcomes assessed in comparisons within intervention centers and between intervention and comparison centers): 1) Comprehensive care will decrease total PICU days; 2) The reduction in serious illness with comprehensive care will be greatest for infants of poorly educated mothers; 3) Comprehensive will increase maternal satisfaction; in intervention centers; 4) Comprehensive care will not increase total care costs as shown by a formal economic evaluation in two Network centers (UT Houston and another yet to be named).

Tertiary Hypothesis (addressing process measures collected only in intervention centers): Assessment of successive infant cohorts will indicate a successively 1) greater % of eligible infants who enroll in the comprehensive care program, 2) greater % of eligible infants who continue in the program through one year of age; 3) a lower number of ED visits expressed as a % of all visits; 4) a lower % of infants who are admitted to hospital without having been previously seen and/or discussed by phone with comprehensive care personnel.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Requirements for comprehensive FU care. Intervention centers will differ somewhat in the services provided and how they are provided in their locale. However, all will meet the following criteria: 1) Staff: Small team of caregivers (physicians +/- pediatric nurse practitioners or physician assistants) highly committed to improving the care of high-risk infants 2) Clinic services: Care for chronic and for acute illnesses (goal: same day) as well as well-child care (immunizations, neurodevelopmental assessment, & anticipatory guidance); 3) Staff availability. Caregivers will be available to provide care in person 8 hr/d for 5 d/wk. Families will have pager access at all hrs to a team member, routinely a primary care provider. When an infant is referred to the ED, the ED physician will be called to discuss the infant's problems and management. Comprehensive care will be provided until at least one year postnatal age.

Support to establish comprehensive FU care. Support to help assure the feasibility of this demanding study will include $1250 capitation per study infant given comprehensive care and $300 capitation per study infant not given comprehensive care. The budget (see below) also includes some start up costs, support for the physician project director at each comprehensive care center and support for training and annual meetings. Clinical services provided to comprehensive care patients will also be billable. As for other NRN studies, support will also be needed from the hospital, Department, or Division. This support can be fostered by the Dallas cost-effectiveness data and by local needs and expected changes in health care funding. In helping to promote such support, we provided a series of questions for discussion by hospital administrators and Department Chairs. (Examples include: Are your PICU beds often full? Do the reimbursements fail to meet the true cost of care for Medicaid infants? Do you expect reduced reimbursements for PICU care or higher reimbursements for outpatient preventive care? Do you want to reduce ED visits? Are you having difficulty recruiting intensivists? What additional effort and expense is required to recruit and support intensivists than FU clinic personnel? Are there faculty who would want to be involved in this research? Would malpractice risks be reduced by FU clinic that addresses increases augments care, parental concerns and increases their satisfaction? Would a model FU program attract strong community recognition [as in Dallas]?)

As noted below, FU staff will receive support and advice in periodic visits and phone calls from Dr. Heyne who directs a well established program (Dallas) and Dr Evens who recently initiated a program (Houston). To help optimize the care of the infants and promote the career development of FU faculty, Drs. Tyson, Evans, and Heyne would coordinate efforts among NRN FU PIs to conduct systematic reviews of outpatient methods of treating problems common in high risk infants, develop practice guidelines based on best current evidence, and define a research agenda to address important unanswered questions in NRN observational studies or trials. We also expect multiple publications describing and relating the process and outcome measures in this T3 study

Study Phases: As described below, five infant cohorts discharged in successive 6 mo periods will be studied:

- 2/01/10 – 7/31/10: Control Cohort 1 (f/u to ~4/3o/11)
- 8/01/10 – 1/31/11: Control Cohort 2 (f/u to~10/31/11)
- 2/01/11 – 7/31/11: Intervention Cohort 1 (f/u to ~4/3o/12)
- 8/01/11 – 1/31/12: Intervention Cohort 2 (f/u to ~10/31/12)
- 2/01/12 – 7/31/12: Intervention Cohort 3 (f/u to ~4/30/13) allowing 3 months for completion of analyses, submission of the primary manuscript, and initiation of the dissemination plan before completing the funding period (8/30/13).

The study will be conducted as follows:

Before 8/1/10 (anticipated start of funding). Completion within 3 yrs of funding will be feasible because of extensive prior planning and the Network resources and research infrastructure. The concept proposal has been approved by the NRN and discussed in depth at 3 meetings and by phone with individual PIs and Follow-Up PIs. Further discussion and planning will occur during visits by Drs. Evans &/or Heyne to the 7-8 intervention centers. To help assure that all important issues have been carefully considered in planning the study, we will

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

have prepared a draft of the introduction and methods section and a skeleton of the tables for the final manuscript for the study.) Prospective data collection will begin for **Control Cohort 1,** control infants meeting exactly the same criteria as infants targeted for comprehensive care in the same center and discharged on or after 8/1/09-1/31/10.

8/01/10 – 1/31/11**:** Preparation phase with personnel hiring and training for comprehensive care in intervention sites. All sites will initiate data collection for **Control Cohort 2** (control infants) discharged during this time and continue data collection for Cohort 1.

02/01/11 -7/31/11 Initiation of comprehensive care; enrollment of **Intervention Cohort 1** (study infants discharged during this period); data collection to be completed for Control Cohort 1 and continued for Control Cohort 2.

8/01/11 – 1/31/12: Enrollment of **Intervention Cohort 2** (study infants discharged during this period). Data collection will be completed for Control Cohort 2 and continued for Intervention Cohort 1.

2/01/12 – 7/31/12: Enrollment of **Intervention Cohort 3** (study infants discharged during this period). Data collection will be completed for Intervention Cohort 1 and continued for Intervention Cohort 2.

8/01/12 – 1/31/13 Data collection will be completed for Intervention Cohort 2 and largely completed for Intervention Cohort 3. Audits and data cleaning will be completed for all collected data.

1/31/13-7/31/13 Depending on when the last infant reaches 12 months age, data collection will be completed for all cohorts by ~ 4/30/13. Audits, data cleaning, data lock, and data tables will then be quickly completed. As for other Network studies in which Dr. Tyson was responsible for preparing the primary manuscript, it would be promptly prepared (building on the draft of the introduction, methods, and data table skeletons prepared before initiating the study) and ready for internal review by no later than 7/1/13 and submission for publication within 1-2 months.. Dissemination of results would begin as soon as the final analyses were completed and would be well underway by the end of the funding period 8/31/09.

Outcome and Process Measures. The proposed research has been designed to assure collection of important outcome and process measures while minimizing the time, effort, and expense required for data collection.

- All sites: For all eligible infants as described above, data collection would include data items included in the Network generic data base, maternal education at discharge, and the following data items between hospital discharge and one year age: death, PICU admission, PICU days, hospital admission, and total hospital days to 12 months age. (Hospital admissions will be identified by local records, maternal report and Medicaid records [with consent to access these records obtained at enrollment to the study]).
- Intervention sites will also collect
    - Percent of infants in each cohort who enroll in comprehensive care during each intervention period and percentage who continue in the program through one year of age
    - Percent of infants lost to follow-up at one year of age
    - Number of ED Visits
    - Visits/phone calls
    - Maternal satisfaction with care after NICU discharge, using an adaptation of the CAHPS Clinician and Group Survey Child Primary Care Questionnaire" from AHRQ.
- Three selected intervention sites, including UT Houston:
    - Detailed economic data concerning cost of all inpatient care and of comprehensive vs. routine follow-up program outpatient care as specified by the involved health care economist (Luisa Franzini, PhD, UT Houston School of Public Health).

Statistical Analyses. The analyses will be performed by Research Triangle International. To test Hypothesis 1 that severe illness will be progressively reduced in intervention centers, hierarchical analyses will be performed using data from all high risk infants intended to receive comprehensive care (whether or not they received it) among intervention centers. The dependent (outcome) variable will be serious illness, and the independent (predictor) variables will be time period, season at discharge, center, maternal education, and other important

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

social and medical variables at discharge predictive of severe illness. (To assure unbiased analyses, these variables will be selected based on univariate models and clinical judgment before performing the logistic regression analyses). A progressive reduction in serious illness would be identified by a negative slope when relating risk adjusted incidence of serious illness to period. To test Hypothesis 2, multi-level analyses will be performed using all infants from intervention and control sites who qualify for generic follow-up (see above). The dependent variable will be serious illness and the independent variables will be patient outcomes will be group (comprehensive care or comparison), period, maternal education, medical variables at discharge predictive of serious illness (selected as above). Hierarchical logistic analyses will assess group effect after controlling for individual and center level covariates.

In accordance with recent recommendations for clinical trials,[6] Bayesian as well as frequentist analyses will be conducted by Dr. Pedroza (who conducted the analyses for a recent NRN publication in the New England Journal of Medicine.[7] Prior probability and 95% credible intervals will be based on values elicited from the Network PIs and FU PIs provided relevant literature.

Sample Size and Interpretation of Results: We expect intervention centers to provide comprehensive care to approximately twice the number of infants they would see for generic NRN follow-up. (Based on follow-up data for infants ≤26 wks GA born in 2006 and the Network generic neonatal data for the number of survivors <29 wks GA, this could be achieved simply by following infants 27-28 weeks, if not also high risk infants born at a later GA who developed specified complications.) If so, the number of patients given comprehensive care in the proposed study is expected to equal or exceed that in the large Dallas trial. With the control cohorts in both the intervention centers and the control centers, the number of infants given usual care will be approximately two fold that in the Dallas trial. However, in a 3 year study, the power for frequentist analyses will be limited by the number of infants who can be enrolled and the need to control for center differences. For this reason, it is possible that there will be no statistically significant reduction in serious illness, particularly for the second primary hypothesis that would be tested only in infants ≤26 weeks gestation. However, we expect that Bayesian analyses would support the benefit of comprehensive care. As long as there is no evidence that serious illness is increased by comprehensive care, the study findings could justify recommending comprehensive care as a method that increases access to care, provides a medical home during a period when high risk infants are especially prone to serious illness, decreases loss to follow-up, and augments parental satisfaction without increasing cost.

Budget. CHOICE grant funding for this project will be requested from AHRQ, including:

1) Capitation: approximately $750,000, depending on sample size:
    a. $1,250 per comprehensive care intervention subject to cover research related costs and some training, incremental personnel, and other implementation costs.
    b. $300 per control subject at intervention and control centers to cover research costs including data collection and reporting
2) Non-capitation; Approximately $2,500,000 to cover
    a. PI (Tyson) + 2CoPI (Heyne and Evans) support (25% for the PI as required by the RFA and 20% for the CoPIs)
    b. Physician Project Director costs for 7-8 intervention centers (15% each)
    c. Provider training not covered by capitation
    d. Incremental clinic costs for providing comprehensive care
    e. Economist (33%), Luisa Franzini)
    f. Data entry
    g. Dissemination costs

RTI costs are yet to be determined.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Estimated total project cost: $3,250,000 excluding RTI costs and indirect costs. The grant can cover costs incurred during the 90 days prior to the start of the funding period.

DATE: November 24, 2009

TO: Jon Tyson, MD, Patricia W. Evans, MD, Roy Heyne, MD, Claudia Pedroza, PhD, and Luisa Franzini,PhD

FROM: Richard A. Ehrenkranz, MD
Chair, Protocol Review Subcommittee

RE: Comprehensive Follow-Up Care of High-Risk Infants – A T3
Comparative Effectiveness Study

The Protocol Review Subcommittee reviewed this protocol during its conference call on November 23, 2009. Written comments were provided by Brenda Poindexter, Michael Acarregui, Abhik Das, Jim Zhang, and Rose Higgins; those comments are attached to this summary.

As you will appreciate from the reviewers' comments below and from Rose's brief email following the conference call, the Protocol Review Subcommittee considered many issues related to the design and feasibility of this proposal, including:

1. The proposal lists "5 infant cohorts discharged in successive 6 month periods" beginning 2/01/10-7/31/10. However, since the earliest date for the start of AHRQ funding would be September 2010, and since most intervention centers and RTI will not be able to initiate study related activities until funding is provided, the study's timeline should be revised and made consistent with the AHRQ timeline.

2. Consider including a table in the application that lists the current "primary care" practices provided by the likely intervention centers and the care elements that would be added as part of the comprehensive follow-up care initiative.

3. Specify a clear definition of the infants eligible to receive comprehensive follow-up care in intervention centers. As written, this aspect of the application is too vague and would permit each intervention center to define its potential population. While that strategy might be the best "real world" approach (and eventually how this concept might be generalized), it will make interpretation of the study's results quite difficult. It is also important to note that the data system for non-GDB study infants will be built upon the current system and that a new data system will not be designed.

4. It appears that the intervention centers have been self-selected. Therefore, the comparison, ie control, centers may differ markedly from the intervention centers, for example due to the involvement and/or availability of developmental pediatricians, pulmonologists, and private pediatricians which diminishes the need for a comprehensive follow-up care program. Furthermore, the existence of such center-specific characteristics may prevent an otherwise interested center from choosing to be an intervention center. As you are probably aware, there is a lot of potential for selection bias in the current study design. Therefore, the method in which centers will be selected to be intervention or comparison centers should be clarified.

Normally, the Protocol Review Subcommittee would request that a revised protocol be submitted to the Subcommittee before recommending that it be considered by the Steering Committee. However, given the AHRQ submission deadline of December 16, 2009, the limited time available for the investigators to revise this proposal, and the Subcommittee's level enthusiasm if this study

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

were funded by AHRQ, the Subcommittee recommends that it be considered during the monthly Steering Committee conference call on November 24, 2009. Furthermore, the Subcommittee recommends that a letter stating that the NRN infrastructure may be used in the performance of the comprehensive follow-up care study, if it is funded by AHRQ, accompany the application. We hope that the comments contained in this summary review will be helpful in your efforts to revise the application.

Comments submitted by Brenda Poindexter:

The proposal is for a comparative effectiveness trial of a comprehensive follow-up care program versus standard care of extremely premature infants. The primary hypothesis is that comprehensive care will reduce serious illness (defined as death, PICU admission, or prolonged hospital stay) between discharge from a NICU and before 12 months after birth.

The rationale for this proposal is compelling given the results of the previously published study conducted in Dallas. However, as the investigators point out, it is not clear how generalizable the results of the Dallas study will be to other locales.

The study design is unique in that outcomes will be assessed in successive infant cohorts, providing intervention centers the opportunity to not only introduce, but also refine comprehensive care in their particular setting. Infants discharged from the intervention center will be assessed in 6-month periods – the first two periods will be pre-intervention control periods followed by three intervention periods. Infants at comparison centers that do not provide comprehensive care will similarly be assessed in the same five 6-month periods of time.

Overall, I am enthusiastic about this protocol and think that the rationale and evidence for comprehensive care is strong. The majority of my comments relate to implementation of comprehensive care. If the investigators are able to secure funding outside of the Network with a CHOICE grant from the AHRQ, I would support the proposal moving forward.

COMMENTS:

1. Study Population: The protocol states that centers can choose to provide comprehensive care not only to infants born at <26 weeks gestation, but also to other predefined high risk groups of infants – given the complexity of introducing and refining a new paradigm of care, it would seem that all centers should begin with the same focused group of eligible infants (those <26 weeks) for at least the first intervention period; once the comprehensive care model is well-established, other high-risk groups of infants could then be added depending on availability of funding to do so. Also need to better define the geographic boundaries for eligible infants.
2. Informed Consent: When would consent be obtained for the protocol? Given the prospective data being collected, I would surmise that most IRBs would require consent. I would be interested to hear the investigators thoughts on this.
3. Subspecialty care: In the model of comprehensive care, how are consulting subspecialists integrated into the model? For example, at many centers, the developmental pediatricians (same individuals who staff the follow-up visit at 18 months) are already seeing these high-risk babies for transition to oral feeds as early as 2-4 weeks following NICU discharge. In addition, many infants with BPD are followed by Pediatric Pulmonologists if they go home on oxygen. Would the intent be for the comprehensive care pediatrician to take the place of these subspecialists or rather to coordinate care and provide a "medical home"?

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

4. Comparison centers: Much of the information needed to assess outcomes will be difficult to obtain from infants who are not being seen in the comprehensive care model (those at control centers and those at intervention centers in the first two control cohorts). I would assume that many of the centers have more than one ED where these infants might go for urgent care. How do the investigators propose that infants in the comparison cohorts (both at comparison centers and during the first two cycles at intervention centers) be tracked?
5. Role of teaching residents: I assume that all of the participating Network centers have resident clinics that are currently the primary care providers for many of these high-risk infants. How could residents potentially be integrated into the comprehensive care model?

Comments submitted by Michael Acarregui:

The current proposal is a multicenter, comparative effectiveness trial of comprehensive versus traditional follow up of NICU graduates of <27 weeks gestation with an option to enroll and include infants < 29 weeks. The primary outcomes are illness resulting in death, PICU admission and prolonged hospital stay through one-year postnatal age. In addition to the two lead centers (Dallas and Houston) 7-8 intervention centers will enroll infants into a comprehensive care follow up program that includes the provision of all primary care (8 h, 5 days per week) plus 24 h, 7 day per week on call availability of a care provider who can take a call and make referral to a local ER if needed. The study will progress with the enrollment and follow up of 5 successive 6-month cohorts including the initial two control cohorts. Concurrent control patients will also be followed at intervention and other NRN centers. Funding will be provided by capitation of enrolled patients and to fund Project Director costs at intervention centers, training costs and incremental clinic costs.

Comments

1. A successive design is proposed in order to account for changes that will occur in care provided by intervention centers as they refine their center approaches to comprehensive care. What is not clear is how this design will affect the numbers needed to enroll. This will depend on the comparisons to be made in the data analysis. Will the three intervention cohorts be evaluated as a single group or will each cohort be analyzed separately? If separately, will more patients be needed in the early cohorts as there may not be as much difference in the outcomes between intervention and control patients since the comprehensive care may not be fully refined? If analyzed as a combined cohort, then is it necessary to even study successive cohorts? Additionally, the use of two initial cohorts as controls will result in an historical cohort for comparison. This may not be the most useful comparison as the care of those not in the comprehensive care cohort at intervention centers may benefit from the increase in care infrastructure that will be inevitable as a result of participation as an intervention center.

2. The protocol initially states that the enrollment of infants >26 weeks will be optional but later indicates that the number to enroll should be twice the number of infants under 27 weeks. These numbers will only be achieved by enrolling infants under 29 weeks. Therefore, enrollment of infants < 29 weeks should be a study requirement. This is important not only to increase study numbers but to recognize that these infants are also extremely vulnerable to illness and at risk for rehospitalization. If the study results are to be generalizable to an "at risk" population then it is important to not just include those at greatest risk (<27 weeks).

3. If infants outside the GDB are to be enrolled, can outborn patients be included?

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

4. Outcome Measures are appropriate. I do wonder if it would be important to compare growth parameters age 18-22 months for the GDB patients as a potential indicator of efficacy of comprehensive care as it could also be hypothesized that closer follow up with individuals focused on the needs of ELBW patients will see that the nutritional care is optimized in these patients.

5. Will it be permissible to refer to any ED or only the center ED at times when the clinic is not open?

6. When will patients be enrolled in the study? Perhaps best to approach a month or so prior to anticipated discharge so that other arrangements for post discharge care have not already been made at the time that patients are approached for informed consent for this study.

7. Analysis of the data should also be stratified by gestational cohorts <27 weeks and 27-28 weeks as the greater gestational age cohort will likely have more time in follow up (average discharge at an earlier postmenstrual age) than the earlier gestational age cohort that will likely be discharged at a later postmenstrual age.

8. The proposed budget includes items for capitation and non-capitation. The amounts proposed under capitation seem appropriate but may change significantly as sample size calculations are performed. The cost items that are to be covered by this capitation should be better delineated. For the non-capitation items the need for the approximate figure of $2.5 million is less clear as PI and Project Director support will amount to about 1.85 fte or about $450,000 in direct costs. I assume that item "d. Incremental clinic cost..." will include salary support for nurse practitioner or other provider support. This needs to be clarified in the application. Will participating centers submit individual requests for funding their specific study needs?

Overall, this is an interested and much needed study. Given the NRN infrastructure for follow up the study should be feasible. The greatest challenge is to make it relevant to the many that care for these infants and to policy makers. The demonstration of efficacy is in no way adequate to assure adoption of the therapy or approach to care. It will be important to delineate just what it is that makes these follow up clinics "special" and "expert" in the care of this patient population. If general pediatricians are providing this care with the assistance of multiple sub specialists, then how is that different from having a general pediatrician in the community manage the patients in the same manner?

Comments submitted by Abhik Das:

A T3 design seeks to assess how to most successfully provide effective methods of care in different practice settings. These studies are primarily meant to test what *system approaches/changes* are most effective at increasing the delivery of a new and proven intervention to the right patients at the right time, and then disseminate effective strategies. I don't see the stated primary hypotheses doing that. They are more traditional T2 hypotheses concerned with efficacy.

The 1st hypothesis is a before/after design [what has also been called a Non Equivalent Control Group (NECG) design], but there is no discussion of the biases (such as any other changes over time that may impact outcomes) that may entail. It is not clear why we need the study entrants divided into so many cohorts (two for control and three for intervention), and why control cohort(s) are enrolled before the intervention cohort(s). It seems like here we have clustering of patient

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

within time period. Do we assume there are correlations among patients within the same time period? We also need indicator for whether the time period is in the control or intervention period. What center characteristics do we need to adjust for, because this will be very critical? Do we need to collect specific center level data for this purpose? More details laid out in the analysis plan (preferably in terms of regression equations) would be helpful in understanding exactly what is planned.

A rigorous and unbiased test of the 2nd hypothesis is difficult without a cluster randomized design where sites would be randomized to comprehensive care or usual care. If that is not feasible, NECG designs (sometimes also called quasi randomized designs) usually take great care to match sites in some way before assigning selected ones to the intervention. (There is a whole body of literature on NECG and quasi experimental designs that can be profitably explored for better designing this study.) The proposal mentions that center will be controlled in the analysis. This can't be done in the conventional manner with this design since the centers are embedded within the treatment groups, unless this refers to adjusting for a cluster effect.
With respect to the proposed Bayesian analysis, prior elicitation is complex and we need more details here. Using a non-informative prior alongside is also recommended. In this connection, the stated expectation that Bayesian analysis will show a benefit for comprehensive care needs to be quantified.

The proposal says that the analysis will be done at RTI but also says Dr. Pedroza will do "Bayesian as well as frequentist analysis". I am not sure how that is going to work. We need a clear understanding of this beforehand both to convince reviewers at AHRQ of the merit of this application (some reviewers may find statisticians at both institutions as duplicative), and to avoid misunderstanding later on.

The sample size discussion is weak. Doing a parallel Bayesian analysis does not absolve the need to have sufficient sample size to provide credible results. At a minimum, there has to be some notion of expected effect size and power available given the expected sample size for both the primary outcomes, so that the NRN has some idea of the probability of this study generating usable results. We also need these numbers to establish credible enrollment time lines. Specifically, the following issues need addressing:

First, there is little information on the exact number of hospitals that will be included in the study. There is no discussion of how these centers will be selected. The suggestion that six or seven intervention centers would need to be identified, recruited, and receive training prior to the beginning of data collection in 02/2010 is a strong and unsupported assumption. This problem is further complicated by the suggestion of comparison centers with no mention of their potential number or the criteria for their inclusion. Would comparison sites truly be comparable to intervention sites? One would assume that intervention sites would be chosen for a number of logistical factors including their willingness to host a NRN comprehensive follow up care unit.

Second, there is no estimate of the number of infants receiving comprehensive and standard follow up care. The sample size section offers that intervention centers would provide comprehensive care to approximately twice as many infants as they would for a generic NRN follow up. Is this a realistic assumption? This concern is amplified by the lack of specificity regarding location of intervention and comparison centers. Additional concerns involve the ability of the intervention centers to provide comprehensive care (or not provide comprehensive care) on a case by case basis. This stands as a serious threat to the conclusion validity of the study. One could easy anticipate well intentioned practitioners steering comprehensive follow up to those

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

infants they judge will benefit the most from additional services rendering comparisons non-equivalent.

Third, there is no discussion of the impact of clustering on sample size. Even if we are able to recruit large numbers of participants in each center, the statistical power for a clustered design is based on the number of clusters, not the number of individuals, observed. The design includes around 8 centers in each arm of the trail, with five cohorts in each center. Have these implications been considered in planning the trial?

Comments submitted by Jim Zhang (NICHD Epidemiologist):

It is an interesting and potentially important study. From a study design perspective, I have the following questions and comments for consideration:

- Will the investigators use one-sided or two-sided statistical test for their main hypothesis?
- The investigators intend to employ two types of controls: internal and external controls.
- For internal controls: Will there be a period of overlap between conventional FU (controls) and comprehensive FU (intervention)? If the same team of researchers conduct both conventional and comprehensive FU at the same time, would "contamination" of intervention be a concern in this particular study?
- For external controls: Are the investigators able to show if the intervention and control centers are compatible in terms of baseline characteristics of the hospital and newborns using existing database data?
- One would assume that an intent-to-treat analysis will be used. Participation rate (receive the treatment) and retention rate (stay in the program to completion) may become an important issue for such an analysis. Could the investigators make any assumptions based on their previous experience?
- The statistical power and sample size calculation may be affected by several sources of complications: a) hospital clustering of the treatment (equivalent to a cluster randomization); b) participation and retention rates; c) potential protocol variation among the centers.
- In the analysis, it would be more advisable to use the two types of controls separately rather than to mix them together.

Comments submitted by Rose Higgins (sent to Jon before the call, who participated at the beginning of the call):

I have a couple of budget questions in advance of this afternoon's call - Do you have a line item for indirect costs?
The protocol states $1250 for each infant with comprehensive care, but the spreadsheet says $1500. I assume you want the 1500, correct?

Do you have a budget for the RTI costs to include coordinator time, programmers, statistician and PI?? (+indirects) Is it the line item marked b. RTI: Data Mgt., Stat Analyses, Prog.Admin?

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

For the travel, I assume the 3 meetings for the 13 individuals are training and updating, correct? We have used $2000 per travel/training meeting due to increased airline costs.

Also, it is my understanding that protocol review (and ultimately the steering committee) would agree to the following as part of the AHRQ application:

The NRN supports this application and can provide the following:
Data Management system for GDB and FU as per the NRN GDB and FU studies. Additional data and data management to support this study are needed.

Current infrastructure at sites and data coordinating center provides a platform for which additional projects can be performed pending availability of additional funding to support these costs

You can either respond by email or join the call at 4 PM ET (866-675-3256 with pass code 560152#) to answer the questions.

Also - minor points -
Can we say "parental" satisfaction instead of "maternal satisfaction?"
For the infants < 29 weeks but > 26 weeks, how much information will be collected? Will the tracking and collection of information occur at the same time?
Can you develop a flow diagram of the control and intervention cohorts?

This is how the policy reads now for Primary Studies:

More than one author from a participating center
A second author from a participating Center, who has special expertise and/or contributes significantly to the development of a protocol, may be nominated by the Principal Investigator of that site. This second author must be approved by the study subcommittee and the Steering Committee. If the Steering Committee approves the inclusion of two authors from the same Center, the Center Principal Investigator will decide who will be listed as the first author from that center. If the second author nomination is rejected by the Steering Committee, the Principal Investigator of that site will determine the single author from the site.

Should it be changed?

Hi
A request is being made to include a second author, Ambal, from University of Alabama on both SUPPORT papers. As you are probably aware, Alabama was the highest recruiter in the trial with 184 of the 1316 infants enrolled. Ambal took charge of SUPPORT recruitment when Wally was not available and was instrumental in the performance at the Alabama site.

Please send me a yes/no vote to include Ambal by 11/25

Thanks
Rose

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-present).

for the NICHD Neonatal Research Network

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-present).

Alpert Medical School of Brown University and Women & Infants Hospital of Rhode Island (U10 HD27904) - William Oh, MD; Angelita M. Hensman, RN BSN; Dan Gingras, RRT; Kim Francis, RN; Dawn Andrews, RN; Kristen Angela, RN.

Case Western Reserve University Rainbow Babies & Children's Hospital (U10 HD21364, GCRC M01 RR80) - Avroy A. Fanaroff, MD; Bonnie S. Siner, RN.

Thanks Mike
We will relook at these.
I think that we had nade a similar decision in previous iiterations and
then others wanted the p vales in Marie and Anhik - can we review?
Thanks

Importance: High

Hi
A request is being made to include a second author, Ambal, from University of Alabama on both SUPPORT papers. As you are probably aware, Alabama was the highest recruiter in the trial with 184 of the 1316 infants enrolled. Ambal took charge of SUPPORT recruitment when Wally was not available and was instrumental in the performance at the Alabama site.

Please send me a yes/no vote to include Ambal by 11/25

Thanks
Rose

Wally
The manual lists you at the UAB PI for the Study. In view of the phenomenal recruitment, I can send an email vote to the subcommittee for concurrence with adding Ambal – would this be ok?? Let me know so I can do this quickly

Thanks
Rose

Dear Rose:

I noticed that Ambal is not on our list of authors. I apologize for noticing this so late in the process but Ambal was instrumental in recruiting infants and following the protocol particularly when I am out of town. Please let me know if there is a problem in adding him as an author to both papers.

Thanks
Wally

Thanks Marie
This is fine
I would still prefer not to have the ROP data by strata and to replace the Death/ROP with ROP only for our Table 3
Thanks Neil

Neil,

Congratulations on completing this trial - an amazing accomplishment. In the attached I offer a few editing suggestions.

In Table 1, I would not include p values, as these are pre-randomization variables and the interpretation of a non-significant p value is that the difference between groups is not larger than can be explained by chance. But since we know that any differences are explained by chance (i.e., randomization), why do we need p values.

In Table 2, I would not include p values, as any differences cannot be attributed to chance, as they are processes that were prescribed by the protocol with the intention of being different.

In Table 3 I would round the p value to one significant digit.

Thanks so much for your efforts.

Mike

Wally and Rose
Here is the "final" CPAP vs Surf paper
It fits NEJM and incorporates all suggestions although some were opposite so we made some choices.
Please review
Wally can you make sure our definitions for BPD etc are identical??
Thanks
I would like to get these submitted
Please share with me your thoughts
Be well
Neil

Acknowledgements (I sent several questions regarding the boilerplate to Stephanie for clarification with Wally's paper)

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Running head: Early CPAP versus Surfactant and outcomes of prematurity

Key words: CPAP, bronchopulmonary dysplasia, extremely low birth weight infant, neonatal mortality, surfactant

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilation strategy. Infants randomized to surfactant were intubated and received surfactant within 60 min minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was non-significantly reduced in the CPAP group compared to the surfactant group, (48.7% vs 54.1%, RR 0.91, 95% CI 0.83, 1.01, p=0.072 when adjusted for gestational age, center and familial clustering. More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.03).

Conclusions: The use of CPAP is an effective evidence based alternative to intubation and surfactant in preterm infants.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[12] Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI).[3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with RDS .[456] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP.[789]

The recent COIN trial randomized 610 infants from 25 0/7 to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm $H_2$0. CPAP infants were intubated if they met failure criteria.[10] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of **usual** care. There was a significant increase in the occurrence of pneumothoraxces [redacted] in the CPAP group (9.1% vs 3.0%, p=.001), most occurring **especially** within the first 2 days, consistent with the findings of an earlier meta analysis**Error! Bookmark not defined.**, **balanced by** and a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with a non significant decrease in death or BPD at 36 weeks.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

In the SUPPORT Trial **we compared** [redacted] early CPAP to early surfactant for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design. The results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen. [redacted]

The primary hypothesis of this trial was that **among infants of 24 to 27 weeks gestation, early CPAP and a protocol driven limited ventilator strategy, with continuing CPAP in the NICU, as compared to** [redacted] prophylactic/early surfactant and conventional ventilation, [redacted] will [redacted] survival without BPD at 36 weeks.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Eligible infants were **those born at** 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a randomizing center, for whom a decision had been made to provide full resuscitation, and parental consent had been obtained. The infants were randomized within each center to two gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP **device** methodology was used for the delivery room administration of CPAP. CPAP or ventilation with PEEP both at a recommended 5 cm H_2O was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU. CPAP infants were not to be intubated exclusively for surfactant administration in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.[11]

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 > **0**.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

airway pressure (MAP) < 10 cm H2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations CPAP infants were treated using NICU standard practice.

Surfactant Arm: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30 An FiO2 ≤ 35 with a SpO2 ≥88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate ≤ 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable without evidence of clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

baseline occurrence data. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment, as this introduced a clustering effect into the design, and increased the sample sizes **further** by a further 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not powered **to detect** for an interaction effect between the 2 factorial arms.

There was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which **We** assigned the diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support, but **for infants who required < 30% oxygen at 36 weeks we** required demonstration of oxygen dependence by an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks.[1213]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks PMA without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. Continuous outcomes were analyzed using mixed effects linear models. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering. A two-sided P value of less than 0.05 was considered statistically significant.

An independent data safety monitoring committee reviewed, **at four points in time,** the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

DeMets spending functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

The study was approved by Human Subjects Committees at all sites and RTI, the NRN data center. Parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled from Feb 2005 through Feb 2009. Enrollment was temporarily suspended from November 2005 until February 2006 by the DSMB because of concerns regarding the oximetry data; no protocol changes were made. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, or race between the 2 treatment groups (Table 1).

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant. Surfactant, was given to 14.1% of the CPAP versus 51.4% of the surfactant group; 67.1% of the CPAP infants received surfactant in the delivery room or NICU, compared to 98.9% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34.4% of CPAP infants compared with 93.4% of surfactant infants, $p<0.001$, Table 2.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post menstrual age was non-significantly reduced for the CPAP group compared with the Surfactant group, 48.7% versus 54.1%, (RR 0.91, 05% CI 0.83, 1.01, p=0.072) when adjusted for gestational age, center and familial clustering as pre-specified. Death during the hospitalization was 3.2% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata, 23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.034, Table 4. Overall, there was a non-significant reduction in the occurrence of BPD based on the use of supplemental oxygen, from 40.2% for the CPAP arm to 44.3% for the Surfactant arm,(RR 0.94, 95% CI 0.82, 1.06). Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39.2% vs. 40.6%, RR 0.99, 95% CI 0.87, 1.14). Death or Physiologic BPD at 36 weeks in the CPAP group was 47.8% vs. 51.0% for the Surfactant group, (RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room, length of stay, days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but 2 infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who required intubation during their nursery course (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (7.2 % vs 13.2%, p<0.001).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Strata Results: 24 – 25 weeks Gestation

CPAP infants had a significantly lower mortality while hospitalized 23.9% vs. 32.1%. Causes of death are reported in Table 5. There was a significantly higher exposure to postnatal steroids for BPD, 20.5% vs. 13.0%, p=0.023 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata. [redacted] The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[14] or need for surgical intervention for ROP was non-significantly reduced in the CPAP compared to the surfactant infants, (23.3% vs. 31.4%, RR=0.75, 95% CI 0.54, 1.05).

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups, 10.8% vs 10.2%. The CPAP infants required fewer days of oxygen, 44.0 vs 49.5, p=0.035. Significantly fewer infants received postnatal steroids for BPD, 2.9% vs 7.9%, p=0.008.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP intitiated in the delivery room with early surfactant in ELBW infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. Earlier we found that 100% of infants of 23 weeks gestation required intubation in

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

the DR, and decided that such infants would unlikely be successfully treated with CPAP alone.[15] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[16]

Our trial differs from the recently reported COIN trial[10] in that we randomized all eligible ELBW infants irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven limited ventilator strategy with infants who were to receive surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold approach for intubation and the initiation of mechanical ventilation.[6,7] We believed that testing this complete approach would provide a more relevant result as units currently using early CPAP tend to have a higher threshold for intubation.

We prospectively identified safety outcomes that we chose to follow as investigators. These included; the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H2O compared to the use of early surfactant.

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we prospectively agreed to evaluate such interactions and none were found. Both arms of the study were adequately

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was associated with a non-significant decrease in death by 36 weeks PMA or BPD as defined by the need for oxygen at 36 weeks from 54.1% to 48.7%. We also noted a significant 8.2% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.2 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal [redacted] steroids and a reduction in BPD in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Conclusions:

Compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth, infants between 24 and 27 6/7ths weeks gestation assigned to treatment with CPAP and a strategy of limited ventilation have a non significant reduction in the incidence

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

of death or BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse neonatal outcome. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

Marie
I am concerned about any ROP outcome that uses status at Transfer or discharge – unless the infants were judged to be mature by this time- If you have this data and that is what your reporting please let me know. I would not report the ROP outcomes by strata in the CPAP paper. There is indeed far too much missing data and for many infants final eye status was > 55 weeks so that transfer or discharge is a relatively useless time point. Let's leave the ROP to the SpO2 paper.
I am concerned about the number of infants with missing ROP data in this paper and I fear that the reviewers will also be concerned about this. Lets get these papers in and see what they say
Thanks
Neil

Subject: CPAP draft with statistical methods edits

Neil,

Attached is your paper and tables with edits by Abhik and myself. Note that, as in the SpO2 paper, I have re-run the test of the ROP outcome so that it looks at survivors only. Interestingly, that test now favors surfactant in the 26-27 week GA stratum with a p-value of .03. However, since we have so much missing ROP data I would not want to read that much into it, especially since the death or ROP outcome is not significant.

There is one additional edit I did not make to the paper, but which I think is worth considering. Someone on the subcommittee call (I can't remember who) brought up the distinction between "need for oxygen" vs "oxygen use." In terms of how we actually defined BPD in our data, we looked at oxygen use because that is what we capture. Need for oxygen, as the person pointed out on the call, might be more in line with what is captured by the physiologic definition. This is supported by the statement in your paper that the physiologic definition "required demonstration of oxygen dependence by an attempt at oxygen withdrawal." Food for thought.

I will be sending you a new CONSORT figure that includes BPD as well as death so it will match the new version I will be sending Wally that includes ROP and the number of infants missing the final ROP outcome.

Thanks, and have a good weekend.

Marie

Subject: RE: significant p values
Date: Friday, November 20, 2009 10:49:07 AM

Jon
Thank you for your thoughtful comments. As far as reporting the primary outcomes for each paper, neither were significant, so we are following what was written in the protocol regarding the p of 0.02 to be conservative. There was no difference between the two groups, so we are fine with reporting the primary outcome. With respect to the secondary outcomes, there was no p value stated in the protocol for statistical significance. We will report the p values and the RR's with the CI's for the respective secondary outcomes. Since there are no p values indicated in the protocol for secondary outcomes, we can state "signiificant at $p < 0.05$" and be well within the bounds of the protocol. The reader/reviewer can then make their own judgement with respect to the data. The predefined primary outcome analysis is with center, familial clustering and GA strata taken into consideration as described in the protocol. At this point, corrections for further multiple comparisons, though potentially helpful, are likely to hold up reporting of the primary and secondary study outcomes. These data needs to be promptly submitted for publication.

As far as soliciting assistance from independent statisticians, this is something that should have gone through the subcommittee and steering committee. In the vast majority of cases, the steering committee is open and receptive to such assistance. However, this could be perceived by some as undermining the network processes in place. I know that you are very invested in the NRN activities and are passionate about having our results presented in an honest and accurate way.

For the Bayesian analyses, a secondary proposal can be submitted to the SUPPORT Subcommittee. This was not part of the original protocol and would cause a delay in getting the primary papers submitted if we await a proposal, try to set up a call, and review the proposal to include this in the primary papers.

Thanks

To: Wally Carlo, M.D.; Finer, Neil; Abhik Das; Higgins, Rosemary (NIH/NICHD) [E]
Subject: RE: significant p values

Neil, the alpha of 5% would refer to the combined alpha error of the two components (CPAP/limited ventilation vs. intubation/surfactant; high vs low O2 sat goals). The p of 0.02 was labelled as conservative because it was slightly less than 0.025 which added to another 0.025 would be a 0.05 total alpha error for both components combined).

Without indicating what I thought, I copied pg 22-24 and provided these pages independently to two statisticians and asked each to indicate based on the material in the protocol, what p would be considered signficant for the primary outcome and what p would be signfiicant for the secondary outcomes. Each concluded that the protocol

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

indicated the p value considered signficant for the primary outcome would be 0.02 and the p value for secondary outcomes was unstated and ambiguous. Each noted that an argument could be made that if the p for the primary outcome needed to be corrected for multiple comparsions, it was logically inconsistent to use a higher p for secndary outcomes when many more comparisons were performed for seconddary outcomes in each of the two components However, it is true that most studies report what is referred to as a nominal p value of 0.05 for secondary outcomes.

It seems to me that it would be good to perform Bayesian analyses for the primary analyses, death, and when the 18 mo analyses are performed, death or impairment. As we have discussed before, Bayesian analyses have been recommened as supplementary analyses for all clinical trials (Wijeysundera et al J Clin Epi 2009;62:13-2), and they largely, if not entirely, avoid the problems of rather arbitrary decisions about what p values should be considered signficant and whether to correct for mulitple comparisons. I think these would support conclusions currently based on the p values that are being debated and as in the Phototherapy trial, could be conservatively perfromed, described in two sentences in the text and provided in the Appendix for the groups combined and for the two GA strata. Claudia Pedroza could do these promptly. Neil and Wally, how does this sound to you? I'm of course happy to talk about this if you want.

Hi Jon
I have read page 23 and I am unclear. In 2 places it clearly states that alpha is 5%
The 2% appears to refer to calculations for determining sample size or possibly for the interaction tests.
I will wait for Abhik to review
Thanks
Neil

Here is page 23

Hence, for any of the four groups the table below gives the total sample sizes required for a range of absolute percent changes, a two-tailed alpha level test of 5% and for powers of 80% and 90%. The N1 column powers the 2 x 2 factorial for the two primary outcomes and the N2 column assures comparable power for the Death/NDI outcome.
With regard to the power for detecting the interaction between the two factors in the factorial, a fourfold increase in

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

the stated sample size would be required to detect an interaction effect as large or larger as that stated in the table (i.e. the Detectable Difference), assuming the same alpha level and power. The interaction effect referred to is the classical one where the difference in outcome for one of the treatments in the factorial differs according to the level of the other treatment (i.e. the treatment effects are not additive).

If the study is powered for the two primary outcomes and mortality/NDI is considered as a secondary outcome then the table below gives the total sample size required for a 5% overall level test at 80% and 90% power. These represent the total numbers enrolled. To correct for two outcomes, we chose a conservative 2% level of significance and a conservative outcome rate of 50% in making the calculations. These sample sizes are given in the N1 column and would also allow a 10% difference in NDI/death to be detected with a power of 73%. If an 80% power is desired for the NDI/mortality outcome this would result in sample sizes in the N2 column.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Subject: RE: SUPPORT analyses

If we decide to follow the advice from Dennis, we can present the p values as is for death and other secondary outcomes, without interpretation as to statistical significance. The trends remain regardless of what cut-point one chooses to use.

Again, I agree with you and Wally (and Ken) that I had not seen this as an issue because I had viewed the 2% significance assumed for the sample size calculations as something we used to conservatively size the trial, which would not affect the analysis. However, the reactions from Jon and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Dennis now suggest that there may be NEJM reviewers as well who feel differently about this. So, we need to figure out how to proceed. Rose tells me that Wally is out of the country; so I don't know whether he can participate in a call today or tomorrow.

Thanks

Abhik

Abhik
To understand what we need to do - as neither primary is significant do we add to the statistical sections of the methods that we chose a p value =0.02 for the primary? I'm not sure why we can the use a lesser p value for other outcomes like death. Why would we be allowed to do that - what is the logic of a lesser significance level for these??
We need to figure this out
Certainly I was not aware nor where you or Marie about the need for the p to be 0.02 How did we miss this - I have read that section as calculations to develop sample size. Lets arrange a call and figure this out I'll wait for your answers Neil

-----Original Message-----
From: Das, Abhik [mailto:adas@rti.org]

Cc: Higgins, Rosemary (NIH/NICHD) [E]; Gantz, Marie
Subject: RE: SUPPORT analyses

I agree with your interpretation that the analysis was always planned to be at the 0.05 level, but unfortunately the protocol is not explicit about that in the analysis plan, and the NEJM reviewers, if they are nitpicking about it (which they sometimes are), could make an issue out of it. You already have the contrary views on this from Jon and Dennis in previous emails.

As for why 0.02 and not 0.025, I don't have a good answer for that, and one would have to ask Ken, because he did those calculations. Perhaps he was thinking of apportioning the significance at 0.02 each for death/BPD and death/ROP, and 0.01 for death/NDI, to get to an overall trial-wise significance of 0.05.

Thanks

Abhik

Subject: RE: SUPPORT analyses

Abhik and ALL.

As I understood, the p 0.02 was to power the triasl but the analysis was always planned to be 0.05 as these were always thought to be 2 trials.

Why would we have used 0.02 instead of 0.025 for the effect? No one ever takes 0.04. Indeed, we planned two separate primary hypotheses as these were meant to be two separate trials.

Wally

Subject: SUPPORT analyses

Neil and Wally:

We may need a conference call amongst ourselves to resolve the issue of the significance level for the analyses. I heard back from Ken on this issue (his perspective is crucial because he designed the statistical aspects of the trial), and here is what he had to say:

"... We chose the 0.02 level to adjust for the primary outcomes (BPD/death,ROP/death). We could have chosen the less conservative 0.025 but did not. It has nothing to do with the secondary outcomes. And it should have nothing to do with "significance" of the final test of the primary outcomes. They are what they are and should be reported as such."

I agree with Ken that it is ok to use conservative criteria to adequately size a trial, but then use conventional significance levels in the analysis. However, since this was not articulated explicitly in the protocol analysis plan, Dennis sees merit in Jon's arguments on this, and thinks that we may have trouble with the NEJM in this regard. Here is the approach he proposes:

"... simply do the primary short-term outcome (death/ROP) at the 0.02 level (since that appears to be the planned outcome) and describe all other tests that we do as tests of secondary hypotheses for which the p-values are reported descriptively at the per-test level with no interpretation of statistical significance. That would seem to me to avoid the problem entirely."

Materially, whatever approach we take doesn't make much difference because our primary outcome results are not significant either way. Let me know how you want to proceed.

Thanks

Abhik

Hi Jon
I have read page 23 and I am unclear. In 2 places it clearly states that alpha is 5% The 2% appears to refer to calculations for determining sample size or possibly for the interaction tests.
I will wait for Abhik to review
Thanks
Neil

Here is page 23

Hence, for any of the four groups the table below gives the total sample sizes required for a range of absolute percent changes, a two-tailed alpha level test of 5% and for powers of 80% and 90%. The N1 column powers the 2 x 2 factorial for the two primary outcomes and the N2 column assures comparable power for the Death/NDI outcome.
With regard to the power for detecting the interaction between the two factors in the factorial, a fourfold increase in the stated sample size would be required to detect an interaction effect as large or larger as that stated in the table (i.e. the Detectable Difference), assuming the same alpha level and power. The interaction effect referred to is the classical one where the difference in outcome for one of the treatments in the factorial differs according to the level of the other treatment (i.e. the treatment effects are not additive).
If the study is powered for the two primary outcomes and mortality/NDI is considered as a secondary outcome then the table below gives the total sample size required for a 5% overall level test at 80% and 90% power. These represent the total numbers enrolled. To correct for two outcomes, we chose a conservative 2% level of significance and a conservative outcome rate of 50% in making the calculations. These sample sizes are given in the N1 column and would also allow a 10% difference in NDI/death to be detected with a power of 73%. If an 80% power is desired for the NDI/mortality outcome this would result in sample sizes in the N2 column.

ABSTRACT

Background

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The purpose of this study was to quantify the time, effort, and rate of success involved obtaining antenatal consent to enroll infants into the Neonatal Research Network SUPPORT trial, and to determine if these infants were representative of the eligible population.

Methods

Eligible subjects were those likely to deliver in the SUPPORT gestational age window (24-27 6/7 wks). Data included who approached them for consent, how often they were approached, the duration of each contact, whether consent was obtained and if the infant(s) was enrolled in the trial. In addition, all eligible, non-enrolled infants entered into the NRN Generic Database (GDB) throughout the period of SUPPORT enrollment were identified to allow comparison of all infants enrolled in SUPPORT to those who were eligible but not enrolled.

Results

2826 women were identified at 18 sites between October 2005 and February 2009. 2228 were approached for consent and 1219 (54.7%) agreed. For 76.9% of those approached, < 3 visits were required to complete the consent process. (mean 2.0 +/- 1.2). Of the 659 consented infants delivered within the study window, 611 of were enrolled. Mothers who received a neonatal consult were more likely to give consent ($p<.001$). Comparing all GDB infants who were eligible for SUPPORT but whose mothers were not approached (n=2290) to those whose mothers were approached (n=2082), the percentage of infants not exposed to steroids was significantly greater in the non-approached vs. the approached group (20.0%, 3.4% $p<.001$).

Conclusions:

In a trial of preterm infants requiring antenatal consent, more than 5 women were identified as likely to deliver in the GA window for each one who delivered an enrolled infant. The differences between enrolled and non-enrolled infants highlight difficulties in attempting to recruit a representative population for trials requiring antenatal consent.

Introduction:

Informed consent ensures that subjects enrolled in research trials are appropriately informed as to the risks and benefits of the trial, came to the trial voluntarily. Traditionally, this consent is obtained directly from the subject when they are in condition to understand and participate in the process. In conducting trials on infants who will receive an intervention at or near the time of birth, the process requires approaching families prior to delivery.

Funding for clinical trials sponsored by federal agencies and industry is often based on a model of capitation in which a site is paid based on the number of subjects enrolled. Funds may be awarded for screening for eligible subjects, but centers are not usually paid for the time required to seek or obtain consent for subjects who are not enrolled. However, because prospective data comparing the number of families who are approached in the antenatal period to the number of infants who are actually enrolled have not previously been available, the current model may not adequately account for time spent by study staff to screen, approach and enroll all eligible subjects.

The early months of enrollment in the Surfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants (SUPPORT) demonstrated that antenatal screening and consent were labor intensive and that the number of patients enrolled seemed to be much lower than the number screened. Thus, this secondary study was designed to quantify the antenatal screening and consent process to determine the time, effort and other factors that contribute to successful enrollment of patients in a complex trial conducted by an experienced multi-center trials network. The second objective of the study was to determine whether the subjects enrolled in the trial were representative of the overall eligible population.

Methods:

This is a prospective cohort study of the antenatal consenting practices of research personnel in the multi-center Neonatal Research Network (NRN) funded by the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD). Data for this study were collected during the

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

second half of the NRN SUPPORT trial. The SUPPORT trial was designed to compare the use of early Continuous Positive Airway Pressure (CPAP) initiated in the delivery room to early intubation and surfactant given within the first hour of life, in a 2x2 factorial design with randomization to two different target SpO2 ranges during receipt of supplemental oxygen up to 36 weeks post menstrual age (PMA). Eligible infants were those inborn at NRN centers at 24 0/7ths to 27 6/7ths weeks gestational age (GA) without known malformation for whom full postnatal treatment was planned. SUPPORT enrollment began in February 2005 and ended in February 2009.

Eligible subjects for the antenatal consent secondary study were those women whom the Obstetrical/Perinatal staff thought were likely to deliver in the SUPPORT gestational age window. Clinical data were collected by trained research coordinators, and all analyses were performed at a central data coordinating center (RTI International, Research Triangle Park, NC). Research staff collected study data using a one page data collection form. If the parent(s) were not approached for consent, the reason they were not approached was recorded. If they were approached, the staff recorded the total number of times the parent(s) were approached, the number of such attempts that were made by the research coordinator/RN, and whether permission from the obstetrician was obtained to approach for antenatal consent. Because a neonatal consult is often performed as part of clinical management in this population, staff recorded whether a consult was performed, whether the consent was discussed during the consultation, and whether consent was obtained at the time of the consult. In some centers the Institutional Review Board required a consult be completed prior to consent, so this was also recorded. Women who were approached were asked if they were asked to participate in any other studies for themselves or their infants. Finally, the study staff was asked to estimate the time required to obtain a decision regarding consent.

Data were collected at each of the 18 NICHD NRN centers until fifty mothers had delivered within the window at the center. Data forms were keyed by the centers and transmitted electronically to the Data Coordinating Center. As part of the ongoing NRN Generic Database (GDB) observational

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

study, data were routinely collected on inborn infants at NRN centers, including most of those who met the gestational age eligibility criteria for the SUPPORT study. These data were used to identify eligible non-enrolled (non-consented) infants and to evaluate whether infants enrolled in the SUPPORT trial represented the eligible NRN population.

To determine the representativeness of the population enrolled in the SUPPORT trial, data from the GDB were obtained for those infants born at NRN centers during the period of SUPPORT trial enrollment met enrollment criteria for participation in SUPPORT. Eligible but non-enrolled infants had information collected on prenatal care, the use of antenatal steroids and demographic data. These data were compared for infants who were or were not enrolled in SUPPORT to assess whether the trial had enrolled a representative sample of the available population. In addition, comparisons were made between eligible infants whose mothers were or were not approached for SUPPORT. These data were used to determine whether all eligible women were approached and if not, what the reasons for not approaching them were.

We performed bivariate statistical analyses using Chi-Square and Student's t-tests. All statistical analyses were performed using SAS version 9.1.3 (SAS Institute Inc., Cary, NC). A p value of less than 0.05 was considered statistically significant. This trial was approved by the Institutional Review Boards of all participating centers as well as that of RTI.

Results

Between October 2005 and February 2009, a total of 2826 women were identified at 18 NRN centers as being at risk for delivering a premature infant between 24 to 27 6/7 wks GA and otherwise eligible for participation in the SUPPORT trial. Two NRN centers did not participate in the antenatal consent trial and 4 participating centers did not identify 50 eligible women who delivered in the GA window between the start of data collection for the antenatal consent study and the end of the SUPPORT trial. Thirteen centers had more than 50 women deliver in the GA window (range 51 to 90) before they stopped collecting data. All data collected by participating centers have been included in this analysis. Analysis

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

using only the first 50 women from the centers that over-enrolled was not significantly different. Screening, enrollment and consent numbers by center are presented in Figure 1.

2228 women were approached for informed consent. The two most frequent reasons for not attempting to obtain consent were early discharge and a lack of time prior to delivery (Table 2). Common choices within the "other" category in the table were the inability of the mother to give consent, fetal abnormalities, and language barriers that made informed consent impossible. Mothers were considered unable to give consent when in active labor, too young, or having either a mental or physical health issue which precluded them being approached.

A study coordinator or research RN made 74.7% of all approaches. For 76.9% of those women approached, consent was attempted < 3 times. (Overall mean 2.0 +/- 1.2). The frequency of approaches ranged from 1 (n=900) to 11 (n=2) times. The median time spent to obtain a decision regarding consent was less than 1 hour regardless of the decision. The estimated GA at time of screening was not significantly different for those who consented versus those who did not. Of the 2228 mothers approached, 1219 (54.7%) gave consent, and 581 subsequently delivered within the SUPPORT study window. Of these, 536 delivered infants who were enrolled (Figure 2). Forty-eight of the 659 consented infants born in the GA window (7.3%) were not enrolled, usually due to lack of staffing, equipment, or time. Only 19% of those mothers screened delivered infants who were subsequently enrolled in the study. A neonatal consult was performed in 69.7% of cases where the parent(s) were approached for consent. Mothers receiving a neonatal consult were more likely to consent ($p < .001$), but consent was obtained during the consult in only 11.6%.

Comparing all GDB infants who were eligible for SUPPORT but whose mothers were not approached to those whose mothers were approached revealed several important differences (Table 2). Infants of approached mothers were significantly more likely to be non-Hispanic white; to be older, and to have a high school education , private medical insurance, and at least one PNC visit. A significantly higher proportion of eligible infants whose mothers were not approached had no exposure to antenatal

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

steroids compared with infants whose mothers were approached (20.0% vs 3.4%, p<.001). Maternal parity was lower in women who were approached, but gravidity was not significantly different between the groups.

Eligible GDB infants who were not enrolled in SUPPORT and those who were enrolled were also significantly different. Non-enrolled infants had mothers who were significantly less likely to have insurance and to have received prenatal care and were over 4 times more likely to have gone without antenatal steroids (15.7% vs. 3.8%) (Table 3).

Discussion:

To our knowledge this is the first study to evaluate the time and efforts required to approach and obtain antenatal consent from parents for the enrollment of their unborn infants. Our results reveal that 5 families needed to be identified and screened for every one infant successfully enrolled. Only 47.7% of women consented went on to deliver infants in the study window. Though the time needed to obtain consent was collected as a discrete variable, we found that the median was between 30 minutes and 1 hour. Multiplying these bounds by the number of women approached for each enrolled infant (3.6) yields a value for coordinator time required to obtain an enrolled infant at between 1.8 and 3.6 hours. Assuming that the enrollment rate of the SUPPORT trial was equivalent before data collection for the antenatal consent study began suggests that over 2400 hours were spent screening greater than 6000 women and approaching nearly 4800 for consent to enroll 1316 infants in the SUPPORT trial. This estimate includes time spent approaching women who did not consent and consenting women who did not deliver in the window. It does not account for time spent screening women who were not approached for consent.

Morley et al reviewed parental willingness to participate in multiple trials in the neonatal period and found that most (74%) were willing to allow their baby to participate in multiple trials. [1] We had concerns that the burden of being approached for multiple trials, especially since 5 centers also belonged to a maternal/fetal research network, would affect the enrollment in SUPPORT. We found

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

that only 8.4% of women reported having been approached for another trial at the time of the SUPPORT consent discussion, probably because it was an antenatal consent and the window was early in gestation.

Because of the unique attributes of the NRN, we were able to obtain demographic data from the GDB for infants who were delivered in the SUPPORT gestational age window but were not enrolled in the study. Thus, we were able to compare infants who were vs. were not enrolled and those whose mothers were vs. were not approached. The approached vs. non-approached data help us to better understand what part of the population never had an opportunity to be part of the enrollment, and what the reasons were. The enrollment data allow us to compare the population that was enrolled in the trial with those who were eligible but not enrolled. This is the ultimate result of the consent process.

Infants born to women who were not approached for consent were almost 6 times more likely not to have been exposed to antenatal steroids, an intervention known to be associated with better short and longer term outcomes for preterm infants. [2] They were also more likely to be more immature and their mothers were significantly less likely to have insurance and to have received prenatal care.

In a review of NIH funded interventional randomized controlled trials, Charlson and Horwitz found that only half such trials kept any data on subjects who were eligible but not enrolled, and for those trials which collected data only 27% of eligible non-enrolled subjects were a result of subject refusal.[3] The Consolidated Standards for Reporting of Trials (CONSORT) is a document created with the intent of standardizing items reported in trial publications, including a checklist for necessary items.[4,5] The standards require a flow chart of participants to quantify eligible populations but it does not require identifying the demographics of the non-enrolled group or its similarity to the enrolled or consented populations. Following the CONSORT standards in all antenatal consent trials, that is, obtaining basic demographic information for all eligible infants, will help us understand whether similar reduction biases in enrollment occurs in other studies.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Blinding of allocation has always been the benchmark for protecting trials from biased enrollment. Investigators have shown that trials in which allocation to a study group is well concealed more accurately reflect the true study effect than those not well concealed.[6] However, these controls only protect the trial from internal bias, not the selection bias we have seen. It does not affect the external validity or generalizability of the findings to non-study patients. Manning and Silverman have voiced concerns about this type of selection bias, stating that a disproportionate number of vulnerable and deprived families are involved in clinical research.[7,8] Harth and Thong questioned parents who had volunteered in an asthma trial in Australia and concluded that volunteering parents were "significantly more socially disadvantaged and emotionally vulnerable." [9] In a study of recruitment and retention of premature infants into an early intervention trial, Constantine et al found significant enrollment bias in this direction related to race, weight and site. [10,11] In our study, the sociodemographic variables tended to favor the enrolled group. Mitchell and Kline showed a significantly greater proportion of African-Americans, uninsured patients, and Medicaid recipients in the non-participant group in a minimal risk emergency department study.[12] Aagaard-Tillery and the NICHD Maternal Fetal Medicine (MFM) network found that blacks and Hispanics were significantly less likely to allow use of their genetic samples for future studies.[13] In our study, the socio-demographic variables tended to favor the enrolled group.

Our analysis would suggest that under-privileged subjects were less likely to participate. Because this trial included subjects from 18 academic centers with long-term experience in randomized trials and a broad mix of racial, ethnic, and socio-economic populations, it is not likely that the bias represents an intention to include or exclude any group. The logical conclusion is that the many subjects who were not enrolled in this trial, despite the significant time and effort spent by the coordinators to include them, represent a failure of, or an innate problem with, the antenatal-consent process itself. Our observations, along with previous experience in a trial of a delivery room intervention[14], suggest that it may be ethically appropriate to allow trials that compare routinely used interventions to waive

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

the consent process until after birth. This would ensure that the infants enrolled in such a trial do not differ significantly from the overall eligible population and insure the generalizability of the results.

Conclusion

Our prospective analysis of the process of antenatal consent enrollment in the NICHD Neonatal Research Network SUPPORT trial has shown that antenatal screening and consent are labor intensive, that actual patient enrollment numbers may be significantly lower than screening and consent rates, and that the population enrolled as a result of antenatal consent may not be representative of the total eligible population. In this complex interventional trial of preterm infants, nearly 5 women were identified as likely to deliver a baby in the window for every infant enrolled in the trial. Antenatal steroid use was significantly higher among infants enrolled in the SUPPORT study compared to those who were eligible but not enrolled, with a similar difference between infants born to approached and non-approached women. Along with quantifying the time and expense of antenatal consent, these observations point out the difficulties in attempting to recruit a representative population for prospective trials requiring antenatal consent and suggest that greater use of waiver of consent for trials that are low risk may be appropriate for future studies.

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

ABSTRACT

Background

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The purpose of this study was to quantify the time, effort, and rate of success involved obtaining antenatal consent to enroll infants into the Neonatal Research Network SUPPORT trial, and to determine if these infants were representative of the eligible population.

Methods

Eligible subjects were those likely to deliver in the SUPPORT gestational age window (24-27 6/7 wks). Data included who approached them for consent, how often they were approached, the duration of each contact, whether consent was obtained and if the infant(s) was enrolled in the trial. In addition, all eligible, non-enrolled infants entered into the NRN Generic Database (GDB) throughout the period of SUPPORT enrollment were identified to allow comparison of all infants enrolled in SUPPORT to those who were eligible but not enrolled.

Results

2826 women were identified at 18 sites between October 2005 and February 2009. 2228 were approached for consent and 1219 (54.7%) agreed. For 76.9% of those approached, < 3 visits were required to complete the consent process. (mean 2.0 +/- 1.2). Of the 659 consented infants delivered within the study window, 611 of were enrolled. Mothers who received a neonatal consult were more likely to give consent ($p<.001$). Comparing all GDB infants who were eligible for SUPPORT but whose mothers were not approached (n=2290) to those whose mothers were approached (n=2082), the percentage of infants not exposed to steroids was significantly greater in the non-approached vs. the approached group (20.0%, 3.4% $p<.001$).

Conclusions:

In a trial of preterm infants requiring antenatal consent, more than 5 women were identified as likely to deliver in the GA window for each one who delivered an enrolled infant. The differences between enrolled and non-enrolled infants highlight difficulties in attempting to recruit a representative population for trials requiring antenatal consent.

Introduction:

Informed consent ensures that subjects enrolled in research trials are appropriately informed as to the risks and benefits of the trial, came to the trial voluntarily. Traditionally, this consent is obtained directly from the subject when they are in condition to understand and participate in the process. In conducting trials on infants who will receive an intervention at or near the time of birth, the process requires approaching families prior to delivery.

Funding for clinical trials sponsored by federal agencies and industry is often based on a model of capitation in which a site is paid based on the number of subjects enrolled. Funds may be awarded for screening for eligible subjects, but centers are not usually paid for the time required to seek or obtain consent for subjects who are not enrolled. However, because prospective data comparing the number of families who are approached in the antenatal period to the number of infants who are actually enrolled have not previously been available, the current model may not adequately account for time spent by study staff to screen, approach and enroll all eligible subjects.

The early months of enrollment in the Surfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants (SUPPORT) demonstrated that antenatal screening and consent were labor intensive and that the number of patients enrolled seemed to be much lower than the number screened. Thus, this secondary study was designed to quantify the antenatal screening and consent process to determine the time, effort and other factors that contribute to successful enrollment of patients in a complex trial conducted by an experienced multi-center trials network. The second objective of the study was to determine whether the subjects enrolled in the trial were representative of the overall eligible population.

Methods:

This is a prospective cohort study of the antenatal consenting practices of research personnel in the multi-center Neonatal Research Network (NRN) funded by the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD). Data for this study were collected during the

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

second half of the NRN SUPPORT trial. The SUPPORT trial was designed to compare the use of early Continuous Positive Airway Pressure (CPAP) initiated in the delivery room to early intubation and surfactant given within the first hour of life, in a 2x2 factorial design with randomization to two different target SpO2 ranges during receipt of supplemental oxygen up to 36 weeks post menstrual age (PMA). Eligible infants were those inborn at NRN centers at 24 0/7ths to 27 6/7ths weeks gestational age (GA) without known malformation for whom full postnatal treatment was planned. SUPPORT enrollment began in February 2005 and ended in February 2009.

Eligible subjects for the antenatal consent secondary study were those women whom the Obstetrical/Perinatal staff thought were likely to deliver in the SUPPORT gestational age window. Clinical data were collected by trained research coordinators, and all analyses were performed at a central data coordinating center (RTI International, Research Triangle Park, NC). Research staff collected study data using a one page data collection form. If the parent(s) were not approached for consent, the reason they were not approached was recorded. If they were approached, the staff recorded the total number of times the parent(s) were approached, the number of such attempts that were made by the research coordinator/RN, and whether permission from the obstetrician was obtained to approach for antenatal consent. Because a neonatal consult is often performed as part of clinical management in this population, staff recorded whether a consult was performed, whether the consent was discussed during the consultation, and whether consent was obtained at the time of the consult. In some centers the Institutional Review Board required a consult be completed prior to consent, so this was also recorded. Women who were approached were asked if they were asked to participate in any other studies for themselves or their infants. Finally, the study staff was asked to estimate the time required to obtain a decision regarding consent.

Data were collected at each of the 18 NICHD NRN centers until fifty mothers had delivered within the window at the center. Data forms were keyed by the centers and transmitted electronically to the Data Coordinating Center. As part of the ongoing NRN Generic Database (GDB) observational

study, data were routinely collected on inborn infants at NRN centers, including most of those who met the gestational age eligibility criteria for the SUPPORT study. These data were used to identify eligible non-enrolled (non-consented) infants and to evaluate whether infants enrolled in the SUPPORT trial represented the eligible NRN population.

To determine the representativeness of the population enrolled in the SUPPORT trial, data from the GDB were obtained for those infants born at NRN centers during the period of SUPPORT trial enrollment met enrollment criteria for participation in SUPPORT. Eligible but non-enrolled infants had information collected on prenatal care, the use of antenatal steroids and demographic data. These data were compared for infants who were or were not enrolled in SUPPORT to assess whether the trial had enrolled a representative sample of the available population. In addition, comparisons were made between eligible infants whose mothers were or were not approached for SUPPORT. These data were used to determine whether all eligible women were approached and if not, what the reasons for not approaching them were.

We performed bivariate statistical analyses using Chi-Square and Student's t-tests. All statistical analyses were performed using SAS version 9.1.3 (SAS Institute Inc., Cary, NC). A p value of less than 0.05 was considered statistically significant. This trial was approved by the Institutional Review Boards of all participating centers as well as that of RTI.

Results

Between October 2005 and February 2009, a total of 2826 women were identified at 18 NRN centers as being at risk for delivering a premature infant between 24 to 27 6/7 wks GA and otherwise eligible for participation in the SUPPORT trial. Two NRN centers did not participate in the antenatal consent trial and 4 participating centers did not identify 50 eligible women who delivered in the GA window between the start of data collection for the antenatal consent study and the end of the SUPPORT trial. Thirteen centers had more than 50 women deliver in the GA window (range 51 to 90) before they stopped collecting data. All data collected by participating centers have been included in this analysis. Analysis

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

using only the first 50 women from the centers that over-enrolled was not significantly different. Screening, enrollment and consent numbers by center are presented in Figure 1.

2228 women were approached for informed consent. The two most frequent reasons for not attempting to obtain consent were early discharge and a lack of time prior to delivery (Table 2). Common choices within the "other" category in the table were the inability of the mother to give consent, fetal abnormalities, and language barriers that made informed consent impossible. Mothers were considered unable to give consent when in active labor, too young, or having either a mental or physical health issue which precluded them being approached.

A study coordinator or research RN made 74.7% of all approaches. For 76.9% of those women approached, consent was attempted < 3 times. (Overall mean 2.0 +/- 1.2). The frequency of approaches ranged from 1 (n=900) to 11 (n=2) times. The median time spent to obtain a decision regarding consent was less than 1 hour regardless of the decision. The estimated GA at time of screening was not significantly different for those who consented versus those who did not. Of the 2228 mothers approached, 1219 (54.7%) gave consent, and 581 subsequently delivered within the SUPPORT study window. Of these, 536 delivered infants who were enrolled (Figure 2). Forty-eight of the 659 consented infants born in the GA window (7.3%) were not enrolled, usually due to lack of staffing, equipment, or time. Only 19% of those mothers screened delivered infants who were subsequently enrolled in the study. A neonatal consult was performed in 69.7% of cases where the parent(s) were approached for consent. Mothers receiving a neonatal consult were more likely to consent ($p < .001$), but consent was obtained during the consult in only 11.6%.

Comparing all GDB infants who were eligible for SUPPORT but whose mothers were not approached to those whose mothers were approached revealed several important differences (Table 2). Infants of approached mothers were significantly more likely to be non-Hispanic white; to be older, and to have a high school education , private medical insurance, and at least one PNC visit. A significantly higher proportion of eligible infants whose mothers were not approached had no exposure to antenatal

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

steroids compared with infants whose mothers were approached (20.0% vs 3.4%, p<.001). Maternal parity was lower in women who were approached, but gravidity was not significantly different between the groups.

Eligible GDB infants who were not enrolled in SUPPORT and those who were enrolled were also significantly different. Non-enrolled infants had mothers who were significantly less likely to have insurance and to have received prenatal care and were over 4 times more likely to have gone without antenatal steroids (15.7% vs. 3.8%) (Table 3).

Discussion:

To our knowledge this is the first study to evaluate the time and efforts required to approach and obtain antenatal consent from parents for the enrollment of their unborn infants. Our results reveal that 5 families needed to be identified and screened for every one infant successfully enrolled. Only 47.7% of women consented went on to deliver infants in the study window. Though the time needed to obtain consent was collected as a discrete variable, we found that the median was between 30 minutes and 1 hour. Multiplying these bounds by the number of women approached for each enrolled infant (3.6) yields a value for coordinator time required to obtain an enrolled infant at between 1.8 and 3.6 hours. Assuming that the enrollment rate of the SUPPORT trial was equivalent before data collection for the antenatal consent study began suggests that over 2400 hours were spent screening greater than 6000 women and approaching nearly 4800 for consent to enroll 1316 infants in the SUPPORT trial. This estimate includes time spent approaching women who did not consent and consenting women who did not deliver in the window. It does not account for time spent screening women who were not approached for consent.

Morley et al reviewed parental willingness to participate in multiple trials in the neonatal period and found that most (74%) were willing to allow their baby to participate in multiple trials. [1] We had concerns that the burden of being approached for multiple trials, especially since 5 centers also belonged to a maternal/fetal research network, would affect the enrollment in SUPPORT. We found

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

that only 8.4% of women reported having been approached for another trial at the time of the SUPPORT consent discussion, probably because it was an antenatal consent and the window was early in gestation.

Because of the unique attributes of the NRN, we were able to obtain demographic data from the GDB for infants who were delivered in the SUPPORT gestational age window but were not enrolled in the study. Thus, we were able to compare infants who were vs. were not enrolled and those whose mothers were vs. were not approached. The approached vs. non-approached data help us to better understand what part of the population never had an opportunity to be part of the enrollment, and what the reasons were. The enrollment data allow us to compare the population that was enrolled in the trial with those who were eligible but not enrolled. This is the ultimate result of the consent process.

Infants born to women who were not approached for consent were almost 6 times more likely not to have been exposed to antenatal steroids, an intervention known to be associated with better short and longer term outcomes for preterm infants. [2] They were also more likely to be more immature and their mothers were significantly less likely to have insurance and to have received prenatal care.

In a review of NIH funded interventional randomized controlled trials, Charlson and Horwitz found that only half such trials kept any data on subjects who were eligible but not enrolled, and for those trials which collected data only 27% of eligible non-enrolled subjects were a result of subject refusal.[3] The Consolidated Standards for Reporting of Trials (CONSORT) is a document created with the intent of standardizing items reported in trial publications, including a checklist for necessary items.[4,5] The standards require a flow chart of participants to quantify eligible populations but it does not require identifying the demographics of the non-enrolled group or its similarity to the enrolled or consented populations. Following the CONSORT standards in all antenatal consent trials, that is, obtaining basic demographic information for all eligible infants, will help us understand whether similar reduction biases in enrollment occurs in other studies.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Blinding of allocation has always been the benchmark for protecting trials from biased enrollment. Investigators have shown that trials in which allocation to a study group is well concealed more accurately reflect the true study effect than those not well concealed.[6] However, these controls only protect the trial from internal bias, not the selection bias we have seen. It does not affect the external validity or generalizability of the findings to non-study patients. Manning and Silverman have voiced concerns about this type of selection bias, stating that a disproportionate number of vulnerable and deprived families are involved in clinical research.[7,8] Harth and Thong questioned parents who had volunteered in an asthma trial in Australia and concluded that volunteering parents were "significantly more socially disadvantaged and emotionally vulnerable." [9] In a study of recruitment and retention of premature infants into an early intervention trial, Constantine et al found significant enrollment bias in this direction related to race, weight and site. [10,11] In our study, the sociodemographic variables tended to favor the enrolled group. Mitchell and Kline showed a significantly greater proportion of African-Americans, uninsured patients, and Medicaid recipients in the non-participant group in a minimal risk emergency department study.[12] Aagaard-Tillery and the NICHD Maternal Fetal Medicine (MFM) network found that blacks and Hispanics were significantly less likely to allow use of their genetic samples for future studies.[13] In our study, the socio-demographic variables tended to favor the enrolled group.

Our analysis would suggest that under-privileged subjects were less likely to participate. Because this trial included subjects from 18 academic centers with long-term experience in randomized trials and a broad mix of racial, ethnic, and socio-economic populations, it is not likely that the bias represents an intention to include or exclude any group. The logical conclusion is that the many subjects who were not enrolled in this trial, despite the significant time and effort spent by the coordinators to include them, represent a failure of, or an innate problem with, the antenatal-consent process itself. Our observations, along with previous experience in a trial of a delivery room intervention[14], suggest that it may be ethically appropriate to allow trials that compare routinely used interventions to waive

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

the consent process until after birth. This would ensure that the infants enrolled in such a trial do not differ significantly from the overall eligible population and insure the generalizability of the results.

Conclusion

Our prospective analysis of the process of antenatal consent enrollment in the NICHD Neonatal Research Network SUPPORT trial has shown that antenatal screening and consent are labor intensive, that actual patient enrollment numbers may be significantly lower than screening and consent rates, and that the population enrolled as a result of antenatal consent may not be representative of the total eligible population. In this complex interventional trial of preterm infants, nearly 5 women were identified as likely to deliver a baby in the window for every infant enrolled in the trial. Antenatal steroid use was significantly higher among infants enrolled in the SUPPORT study compared to those who were eligible but not enrolled, with a similar difference between infants born to approached and non-approached women. Along with quantifying the time and expense of antenatal consent, these observations point out the difficulties in attempting to recruit a representative population for prospective trials requiring antenatal consent and suggest that greater use of waiver of consent for trials that are low risk may be appropriate for future studies.

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-present).

Alpert Medical School of Brown University and Women & Infants Hospital of Rhode Island (U10 HD27904) - William Oh, MD; Angelita M. Hensman, RN BSN; Dan Gingras, RRT; Kim Francis, RN; Dawn Andrews, RN; Kristen Angela, RN.

Case Western Reserve University Rainbow Babies & Children's Hospital (U10 HD21364, GCRC M01 RR80) - Avroy A. Fanaroff, MD; Bonnie S. Siner, RN.

Cincinnati Children's Hospital Medical Center University of Cincinnati Hospital and Good Samaritan Hospital (U10 HD27853, GCRC M01 RR8084) - Edward F. Donovan, MD; Vivek

Subject: RE: Request for Dr. Solomon NEJM

Small suggested changes are inserted in the attached. Should we also say that ideally we would like to see both papers published in the same issue, or do we not want to go there?

Thanks

Abhik

Subject: Request for Dr. Solomon NEJM

Hi,
Attached is a brief request from Dr. Solomon at NEJM. Let me know if you have specific comments. I can send it to her before the week is out!!
Rose
Rosemary D. Higgins, MD
Program Scientist for the Eunice Kennedy Shriver NICHD Neonatal Research Network Pregnancy and Perinatology Branch CDBPM, NIH 6100 Executive Blvd., Room 4B03 MSC 7510 Bethesda, MD 20892 For overnight delivery use Rockville, MD 20592

Dear Dr. Solomon

The NICHD NRN has recently completed a large multicenter SUPPORT Trial (SUrfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants) with over 1300 infants enrolled into the study.

This prospective, randomized, factorial 2X2 design trial had two main hypotheses:
1). Relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a ~~permissive~~ protocol defined ventilatory strategy in infants of less than 28 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.
2). Relative to infants managed with a higher more conventional SpO2 range (91% to 95%) ~~SpO2 range~~ that the use of a lower SpO2 range (85% to 89%) will result in an increase in survival without the occurrence of threshold ROP and/or the need for surgical intervention.

~~This is a prospective, randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network. The individual factors tested are:~~
~~1) A prospective comparison of CPAP and a permissive ventilatory strategy begun in the delivery room and continuing in the NICU with early (< 1 hour) surfactant and mechanical ventilation.~~
~~2) A prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant is no longer requiring ventilatory support or oxygen.~~

We have two separate papers focusing on the two separate arms of the factorial design ~~, each of which addresses on of the two primary outcomes from the two original hypotheses (ventilation strategy and oximetry)~~ addressing each of the two hypotheses above. We intend to submit both papers to the NEJM. ~~Are~~ Please let me know if there are any special guidelines for reporting studies with factorial designs set forth by NEJM.~~?~~ Your assistance is appreciated in advance.

Best regards,

Rosemary D. Higgins, MD on behalf of the NICHD Neonatal Research Network

Subject: CPAP vs SURF

Wally and Rose

Here is the "final" CPAP vs Surf paper

It fits NEJM and incorporates all suggestions although some were opposite so we made some choices.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Please review

Wally can you make sure our definitions for BPD etc are identical??

Thanks

I would like to get these submitted

Please share with me your thoughts

Be well

Neil

Neil
A couple of comments:
The GA strata analysis probably should be stated as post-hoc.

We should also include a sentence or two about the fact that the surfactant trials particularly the prophylactic trials, were performed in the pre-antenatal corticosteroid era of MFM/neonatology management (late 1980's and NIH consensus conference on antenatal steroids was 1995). Our population had a very high rate of antenatal steroid exposure.

The grant support for each site should list the U10 awards first, followed by the other support. There is no mention of our DSMC in the acknowledgements - did Stephanie send an updated title page for this?? I had asked that this be done.

Thanks for the tremendous effort!!

Hi Jon, Michele, Wally and Rose
I am sending this version for your review. I have not sent it to a wider audience as I would like your views first. This version is NEJM compatible - I think - Perhaps a little sterile but I'll wait for your replies There were many errors, typos and I rewrote quite a bit. I think some of this was from trying to accommodate 15-20 other rewrites. I appreciate everyone's efforts and contribution. No one will need to feel they did not contribute to this manuscript - even with 29 authors.
I have used the Tables so that I haven't quoted the stats but refer to the Tables and included Marie's Consort Diagram and the New Tables As always thanks Marie As for the rest of you - here is your next meal - don't get indigestion!
Neil

Stephanie -
I thought Neil was sent an updated version for the title page and acknowledgements to re-order the grant support (with U10's first) and to list the DSMC members. I don't have access to old emails right now, but I thought we took care of this, right??

Let me know - perhaps I should sent him the updated title page/acknowledgements??

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths to 27 6/7ths weeks gestation. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilation strategy. Infants randomized to surfactant were intubated and received surfactant within 60 minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcomes of death or BPD, using the physiologic definition and death or BPD using the need for supplemental oxygen at 36 weeks were non-significantly reduced in the CPAP group compared to the surfactant group, when adjusted for gestational age, center and familial clustering ((47.8% vs. 51%, Relative risk(RR) =0.95 (0.85, 1.05) p=0.304, 48.7% vs. 54.1%, RR=0.91 (0.82, 1), p=0.072). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001).

Conclusions: CPAP as used in this study is an effective evidence-based alternative to intubation and surfactant in preterm infants.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and death or BPD in preterm infants.[12] Overall prophylactic surfactant has not been reported to significantly reduce BPD alone , whereas early compared with selective later surfactant has been associated with a decreased risk of chronic lung disease.[2] Surfactant not been found to significantly reduce subsequent neurodevelopmental impairment (NDI).[3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with RDS.[456] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP.[7,8,9]

The recent trial by Morley et al randomized 610 infants from 25 0/7 to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H_20. CPAP infants were intubated if they met failure criteria.[10] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analysis[11], and a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006). The primary outcome of death or BPD at 36 weeks was non-significantly reduced in the CPAP arm, 33.9% vs 38.9%, (OR=0.58 to 1.12; P=0.19)

The SUPPORT Trial was designed to compare early CPAP to early surfactant for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design. The results for the oximetry study will be reported separately. The primary hypothesis of this trial was that in infants of 24 to 27 weeks gestation the use of early CPAP and a protocol driven strategy of limited ventilation with continuing CPAP in the NICU infants will result in an increased survival without BPD at 36 weeks compared to infants managed with surfactant within an hour of birth, and a subsequent conventional ventilator strategy.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by a conventional ventilation strategy.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a randomizing center, for whom a decision had been made to provide full resuscitation, and parental consent had been obtained. The infants were

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

randomized within each center to two gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used for the delivery room administration of CPAP. CPAP or ventilation with PEEP, both at a recommended 5 cm H_2O, was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU. CPAP infants were not to be intubated exclusively for surfactant administration in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.[12]

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life, infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a $PaCO_2$ < 65 torr with a pH > 7.20, an SpO_2 > 88% with an FiO_2 < 50%, a mean airway pressure (MAP) < 10 cm H_2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations, CPAP infants were treated using NICU standard practice.

Surfactant Arm: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2 < 50$ torr and pH > 7.30, $FiO_2 \leq .35$ with a $SpO_2 \geq 88\%$, a MAP $\leq$ 8 cm H_2O, ventilator rate $\leq$ 20 bpm, an amplitude < 2X MAP if on HFV, and hemodynamically stable without evidence of clinically significant PDA. Once extubated, Surfactant infants were treated using NICU standard practice.

These criteria for both arms were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN baseline occurrence data (BPD 67%, NDI 61%). We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not powered for an interaction effect between the 2 factorial arms.

There was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which assigned the diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support, but required demonstration of oxygen dependence by an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks. [1314]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks post menstrual age (PMA) without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. Continuous outcomes were analyzed using mixed effects linear models. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering. A two-sided P value of less than 0.05 was considered statistically significant.

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included

death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

The study was approved by Human Subjects Committees at all sites and RTI, the NRN data center. Parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled from February 2005 through February 2009. There were 565 infants enrolled in the lower gestational age strata (24 0/7 to 25 6/7 wks), and 751 in the higher strata 26 0/7 to 27 6/7 wks) (Figure). There were no significant differences for sex, birth weight, or race between the 2 treatment groups (Table 1).

Data regarding delivery room interventions is provided in Table 2. Fewer CPAP infants received positive pressure ventilation in the delivery room compared with the surfactant infants. The Surfactant group received significantly more epinephrine. Intubation in the DR was significantly decreased in the CPAP infants, and 32.9% of CPAP infants never received surfactant during their hospitalization (Table 2).

The primary outcome of death or BPD, using either the physiologic definition or the need for supplemental oxygen at 36 weeks post menstrual age did not reach statistical significance when adjusted for gestational age, center and familial clustering as pre-specified (Table 3).

Death during the hospitalization was non-significantly lower for the CPAP group overall. There was no significant difference in the occurrence of BPD using either the Physiologic Definition or the need for oxygen at 36 weeks (Table 3).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

There were no significant differences overall for death in the delivery room, length of stay, days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but 2 infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who required intubation during their nursery course (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (Table 3). The incidence of severe retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[15] or need for surgical intervention for ROP was not different between the CPAP compared to the surfactant infants (Table 3).

Strata Results: 24 – 25 weeks Gestation

CPAP infants in this strata had a significantly lower mortality while hospitalized 23.9% vs. 32.1%, RR=0.74, (0.57, 0.98), p=0.034 (Appendix Table A1). Causes of death for this strata are reported in Table 4. There was a significantly higher exposure to postnatal steroids for BPD for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants.

26-27 weeks Gestation

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

There was no significant difference in mortality for the CPAP vs Surfactant groups, 10.8% vs 10.2%. The CPAP infants required fewer days of oxygen, and significantly fewer CPAP infants received postnatal steroids for BPD (Appendix Table 2A).

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP initiated in the delivery room with early surfactant in very preterm infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. Earlier we found that 100% of infants of 23 weeks gestation required intubation in the DR, and decided that such infants would unlikely be successfully treated with CPAP alone.[16] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[17]

Our trial differs from the recently reported trial of Morley et al[10~~15~~] in that we randomized all eligible preterm infants irrespective of whether they demonstrated spontaneous breathing and enough respiratory distress to warrant intervention. We also included infants of 24 weeks gestation and compared CPAP and a protocol driven limited ventilator strategy with infants who were to receive surfactant within 1 hour of birth and a conventional strategy. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that units with the most success using CPAP also utilized a higher threshold for intubation and the initiation of mechanical ventilation.[4,5,6] The infants who received surfactant were treated with a ventilator approach that was used by a majority of NRN

units before the trial began. We believed that comparing these two methods would provide more clinically relevant results.

We prospectively identified safety outcomes that we chose to follow as investigators. These included: the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H_2O compared to the use of early surfactant.

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO_2 target range. The randomization resulted in a balance between the infants randomized to each intervention within the pre-specified gestational age strata (Figure, Table 1). While the study was not powered to detect an interaction between the 2 interventions, we prospectively agreed to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was not associated with any increase in death or BPD, or in any adverse neonatal outcomes. BPD using either the physiologic definition or the need for oxygen at 36 weeks was decreased but these differences were not statistically significant. We also noted a significant 8.2% reduction in death in the CPAP infants of our 24 to 25 week strata. While we did not postulate such a difference in the individual strata this increased occurrence of death is cause for concern resulting in a number

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

needed to harm of 12.2 infants for each additional death among surfactant treated infants. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal steroids and a reduction in BPD in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Conclusions:

Infants between 24 and 27 6/7ths weeks gestation assigned to treatment with CPAP have a non significant reduction in the incidence of death or BPD, with no demonstrable increase in any adverse neonatal outcome when compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth. Multiple secondary outcomes including death in the immature strata favored the CPAP group. CPAP as used in this study is an effective evidence-based alternative to intubation and surfactant in preterm infants.

Hi,
You are an author on the SUPPORT OXIMETRY Paper. I need to know if you have any conflict with the publication of this manuscript. Please respond to me with a yes (including specific conflicts) or no by November 19.

Thanks
Rose

NEJM Tables Nov 17 09.doc

Hi Jon, Michele, Wally and Rose

I am sending this version for your review. I have not sent it to a wider audience as I would like your views first. This version is NEJM compatible – I think – Perhaps a little sterile but I'll wait for your replies

There were many errors, typos and I rewrote quite a bit. I think some of this was from trying to accommodate 15-20 other rewrites. I appreciate everyone's efforts and contribution. No one will need to feel they did not contribute to this manuscript – even with 29 authors.

I have used the Tables so that I haven't quoted the stats but refer to the Tables and included Marie's Consort Diagram and the New Tables

As always thanks Marie

As for the rest of you - here is your next meal – don't get indigestion!

Neil

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks gestation. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilation strategy. Infants randomized to surfactant were intubated and received surfactant within 60 minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was non-significantly reduced in the CPAP group compared to the surfactant group, (48.7% vs. 54.1%, RR 0.91, 95% CI 0.83, 1.01, p=0.072) when adjusted for gestational age, center and familial clustering. More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (23.9% vs. 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.03).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Conclusions: CPAP as used in this study is an effective evidence-based alternative to intubation and surfactant in preterm infants.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[12] Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI).[3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with RDS .[456] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP.[789]

The recent trial by Morley et al randomized 610 infants from 25 0/7 to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H_20. CPAP infants were intubated if they met failure criteria.[10] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analysis**Error! Bookmark not defined.**. A reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The primary outcome of death or BPD at 36 weeks was showed non-significantly reduced in the CPAP arm, 33.9% vs 38.9%, (OR=0.58 to 1.12; P=0.19)

The SUPPORT Trial was designed to compare early CPAP to early surfactant for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design. The results for the oximetry study will be reported separately. The primary hypothesis of this trial was that, relative to infants managed with prophylactic/early surfactant and conventional ventilation, use of early CPAP and a protocol driven strategy of limited ventilation in infants of 24 to 27 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a randomizing center, for whom a decision had been made to

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

provide full resuscitation, and parental consent had been obtained. The infants were randomized within each center to two gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used for the delivery room administration of CPAP. CPAP or ventilation with PEEP, both at a recommended 5 cm H_2O, was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU. CPAP infants were not to be intubated exclusively for surfactant administration in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.[11]

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life, infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a $PaCO_2$ < 65 torr with a pH > 7.20, an SpO_2 > 88% with an FiO_2 < 50%, a mean airway pressure (MAP) < 10 cm H_2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant

patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations, CPAP infants were treated using NICU standard practice.

Surfactant Arm: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2 < 50$ torr and pH > 7.30, $FiO_2 \leq .35$ with a $SpO_2 \geq 88\%$, a MAP < 8 cm H_2O, ventilator rate $\leq$ 20 bpm, an amplitude < 2X MAP if on HFV, and hemodynamically stable without evidence of clinically significant PDA. Once extubated, Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN baseline occurrence data (BPD 67%, NDI 61%). We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition

after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not powered for an interaction effect between the 2 factorial arms.

There was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which assigned the diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support, but required demonstration of oxygen dependence by an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks. [1213]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks post menstrual age (PMA) without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. Continuous outcomes were analyzed using mixed effects linear models. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering. A two-sided P value of less than 0.05 was considered statistically significant.

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included

death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

The study was approved by Human Subjects Committees at all sites and RTI, the NRN data center. Parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled from Feb 2005 through Feb 2009. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, or race between the 2 treatment groups (Table 1).

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant. In the delivery room, surfactant was given to 14.1% of the CPAP versus 51.4% of the surfactant group; 67.1% of the CPAP infants received surfactant in the delivery room or NICU, compared to 98.9% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34.4% of CPAP infants compared with 93.4% of surfactant infants, $p<0.001$, Table 2.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post menstrual age was non-significantly reduced for the CPAP group compared with the Surfactant group, 48.7% versus 54.1%, (RR 0.91, 95% CI 0.83, 1.01, $p=0.072$) when adjusted for gestational age, center and familial clustering as pre-specified. Death during the hospitalization

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

was 3.2% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata, 23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.034, Tables 3 and 4. Overall, there was a non-significant reduction in the occurrence of BPD based on the use of supplemental oxygen, from 40.2% for the CPAP arm to 44.3% for the Surfactant arm, (RR 0.94, 95% CI 0.82, 1.06). Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39.2% vs. 40.6%, RR 0.99, 95% CI 0.87, 1.14). Death or Physiologic BPD at 36 weeks in the CPAP group was 47.8% vs. 51.0% for the Surfactant group, (RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room, length of stay, days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but 2 infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who required intubation during their nursery course (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (7.2 % vs 13.2%, p<0.001).

Strata Results: 24 – 25 weeks Gestation

CPAP infants had a significantly lower mortality while hospitalized 23.9% vs. 32.1%. Causes of death are reported in Table 5. There was a significantly higher exposure to postnatal steroids

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

for BPD, 20.5% vs. 13.0%, p=0.023 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata. The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[14] or need for surgical intervention for ROP was non-significantly reduced in the CPAP compared to the surfactant infants, (23.3% vs. 31.4%, RR=0.75, 95% CI 0.54, 1.05).

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups, 10.8% vs 10.2%. The CPAP infants required fewer days of oxygen, 44.0 vs 49.5, p=0.035. Significantly fewer infants received postnatal steroids for BPD, 2.9% vs 7.9%, p=0.008.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP initiated in the delivery room with early surfactant in ELBW infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. Earlier we found that 100% of infants of 23 weeks gestation required intubation in the DR, and decided that such infants would unlikely be successfully treated with CPAP alone.[15] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[16]

Our trial differs from the recently reported trial of Morley et al [10] in that we randomized all eligible ELBW infants irrespective of whether they demonstrated spontaneous breathing and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

enough respiratory distress to warrant intervention. We also included infants of 24 weeks gestation and compared the CPAP and a protocol driven limited ventilator strategy with infants who were to receive surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold for intubation and the initiation of mechanical ventilation.[6,7] We believed that testing this complete approach would provide a more relevant result as units currently using early CPAP tend to have a higher threshold for intubation.

We prospectively identified safety outcomes that we chose to follow as investigators. These included: the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H_2O compared to the use of early surfactant.

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO_2 target range. While the study was not powered to detect an interaction between the 2 interventions, we prospectively agreed to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was associated with a non-significant decrease in death by 36 weeks PMA or BPD as defined by the need for oxygen at 36 weeks from 54.1% to 48.7%. We also noted a significant 8.2% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.2 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal steroids and a reduction in BPD in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Conclusions:

Compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth, infants between 24 and 27 6/7ths weeks gestation assigned to treatment with CPAP as used in this trial have a non significant reduction in the incidence of death or BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse neonatal outcome. Early CPAP is associated with a significant reduction in mortality in the most immature infants. CPAP as used in this trial is an effective evidence-based alternative to intubation and surfactant for very preterm infants.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Dear Dr. Solomon

The NICHD NRN has recently completed a large multicenter SUPPORT Trial (SUrfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants) with over 1300 infants enrolled into the study.

This prospective, randomized, factorial 2X2 design trial had two main hypotheses:
1). Relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a ~~permissive~~ protocol defined ventilatory strategy in infants of less than 28 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.
2). Relative to infants managed with a higher more conventional SpO2 range (91% to 95%) ~~SpO2 range~~ that the use of a lower SpO2 range (85% to 89%) will result in an increase in survival without the occurrence of threshold ROP and/or the need for surgical intervention.

~~This is a prospective, randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network. The individual factors tested are:~~
~~1) A prospective comparison of CPAP and a permissive ventilatory strategy begun in the delivery room and continuing in the NICU with early (< 1 hour) surfactant and mechanical ventilation.~~
~~2) A prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant is no longer requiring ventilatory support or oxygen.~~

We have two separate papers focusing on the two separate arms of the factorial design ~~, each of which addresses on of the two primary outcomes from the two original hypotheses (ventilation strategy and oximetry)~~ addressing each of the two hypotheses above. We intend to submit both papers to the NEJM. ~~Are~~ Please let me know if there are any special guidelines for reporting studies with factorial designs set forth by NEJM~~.~~? Your assistance is appreciated in advance.

Best regards,

Rosemary D. Higgins, MD on behalf of the NICHD Neonatal Research Network

Dear Dr. Solomon

The NICHD NRN has recently completed a large multicenter SUPPORT Trial (SUrfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants) with over 1300 infants enrolled into the study.

This trial had two main hypotheses:
1). Relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a permissive ventilatory strategy in infants of less than 28 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.
2). Relative to infants managed with a higher SpO2 range that the use of a lower SpO2 range (85% to 89%) will result in an increase in survival without the occurrence of threshold ROP and/or the need for surgical intervention.

This is a prospective, randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network. The individual factors tested are:
1) A prospective comparison of CPAP and a permissive ventilatory strategy begun in the delivery room and continuing in the NICU with early (< 1 hour) surfactant and mechanical ventilation.
2) A prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant is no longer requiring ventilatory support or oxygen.

We have two separate papers, each of which addresses on of the two primary outcomes from the two original hypotheses (ventilation strategy and oximetry). We intend to submit both papers to the NEJM. Are there any special guidelines for reporting studies with factorial designs set forth by NEJM? Your assistance is appreciated in advance.

Best regards,

Rosemary D. Higgins, MD on behalf of the NICHD Neonatal Research Network

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/~~7~~7~~ths~~ ~~weeks~~ to 27 6/7~~ths~~ weeks gestation. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilation strategy. Infants randomized to surfactant were intubated and received surfactant within 60 minutes of birth. All infants were also randomized to one of two~~2~~ ranges of SpO2 while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was not~~non~~-significantly reduced in the CPAP ~~group~~ compared to the surfactant group, (48.7% vs. 54.1%, RR 0.91, 95% CI 0.83, 1.01, p=0.072) when adjusted for gestational age, center and familial clustering. More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (23.9% vs. 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.03).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Conclusions: CPAP as used in this study is an effective evidence-based alternative to intubation and surfactant in preterm infants.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[12] Overall surfactant has not been reported to significantly reduce BPD nor neurodevelopmental outcome, but may do so for the most immature infants ~~and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI)~~.[3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with RDS .[456] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP.[789]

The recent trial by Morley et al randomized 610 infants from 25 0/7 to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age and had ~~evidence of~~ respiratory distress ~~at that time~~. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H_20. ~~CPAP infants were intubated if they met failure criteria.~~[10] This study did not compare early CPAP to the early administration of surfactant which ~~, and surfactant use~~ followed unit protocol~~standard of care~~. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with ~~the findings of~~ an earlier meta analysis**Error! Bookmark not defined.**[4]. A reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006).

Comment [rng1]: Sentence fragment

The primary outcome of death or BPD at 36 weeks ~~was showed non-~~ was notsignificantly reduced in the CPAP arm, (33.9% vs 38.9%, (OR=0.58 to 1.12; P=0.19).

The SUPPORT Trial was designed to compare early CPAP to early surfactant for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design. The results for the oximetry study will be reported separately. The primary hypothesis of this trial was that, relative to infants managed with prophylactic/early surfactant and conventional ventilation, use of early CPAP and a protocol driven strategy of limited ventilation in infants of 24 to 27 weeks gestation with continuing CPAP in the NICU will result in ~~an~~ increased survival without BPD at 36 weeks.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen.

Eligible infants were 24 0/7t~~hs~~ to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a randomizing center, for whom a decision had been made to

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

provide full resuscitation, and parental consent had been obtained. The infants were randomized within each center to two gestational age strata, 24 0/7~~ths~~ to 25 6/7~~ths~~ ~~weeks,~~ and 26 0/7~~ths~~-27 6/7~~ths~~ weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used for the delivery room administration of CPAP. CPAP or ventilation with PEEP, both at a recommended 5 cm H_2O, was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU. CPAP infants were not to be intubated exclusively for surfactant administration in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.[11]

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life, infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a $PaCO_2$ < 65 torr with a pH > 7.20, an SpO_2 > 88% with an FiO_2 <0 .50%, a mean airway pressure (MAP) < 10 cm H_2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After three~~3~~ intubations, CPAP infants were treated using NICU standard practice.

Surfactant Arm: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2 < 50$ torr and pH > 7.30, $FiO_2 \leq 0.35$ with a $SpO_2 \geq 88\%$, a MAP < 8 cm H_2O, ventilator rate $\leq$ 20 bpm, an amplitude < 2X MAP if on HFV, and hemodynamically stable without evidence of clinically significant PDA. Once extubated, Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN baseline occurrence data (BPD 67%, NDI 61%). We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not powered for an interaction effect between the two~~2~~ factorial arms.

There was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which assigned the diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support, but required demonstration of oxygen dependence by an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks. [1213]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks post menstrual age (PMA) without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. Continuous outcomes were analyzed using mixed effects linear models. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering. A two-sided P value of less than 0.05 was considered statistically significant.

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

The study was approved by Human Subjects Committees at all sites and RTI, the NRN data center. Parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled from Feb 2005 through Feb 2009. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for gendersex, birth weight, or race between the two 2 treatment groups (Table 1).

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants. The Surfactant group received significantly more epinephrine in the delivery room and had a trend(p=) for higher DR mortality which was not statistically significant. In the delivery room, surfactant was given to 14.1% of the CPAP versus 51.4% of the surfactant group; 67.1% of the CPAP infants received surfactant in the delivery room or NICU, compared to 98.9% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34.4% of CPAP infants compared with 93.4% of surfactant infants(, $p<0.001$), Table 2.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post menstrual age was non-significantly reduced for the CPAP group compared with the Surfactant group, 48.7% versus 54.1%, (RR 0.91, 95% CI 0.83, 1.01, p=0.072) when adjusted for

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

gestational age, center and familial clustering as pre-specified. Death during the hospitalization was 3.2% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata~~,~~ (23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.034), Tables 3 and 4. Overall, there was a non-significant reduction in the occurrence of BPD based on the use of supplemental oxygen, from 40.2% for the CPAP arm to 44.3% for the Surfactant arm, (RR 0.94, 95% CI 0.82, 1.06). Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39.2% vs. 40.6%, RR 0.99, 95% CI 0.87, 1.14). Death or Physiologic BPD at 36 weeks in the CPAP group was 47.8% vs. 51.0% for the Surfactant group, (RR 0.95, 95% CI 0.85, 1.05).

Comment [rng2]: Seems redundant.see above

There were no significant differences overall for death in the delivery room, length of stay, days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but two ~~2~~ infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who required intubation during their nursery course (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (7.2 % vs 13.2%, p<0.001).

Strata Results: 24 – 25 weeks Gestation

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

CPAP infants had a significantly lower mortality while hospitalized 23.9% vs. 32.1%. Causes of death are reported in Table 5. There was a significantly higher exposure to postnatal steroids for BPD, (20.5% vs. 13.0%, p=0.023) for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata. The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[14] or need for surgical intervention for ROP was non-significantly reduced in the CPAP compared to the surfactant infants, (23.3% vs. 31.4%, RR=0.75, 95% CI 0.54, 1.05).

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups(, 10.8% vs 10.2%). The CPAP infants required fewer days of oxygen, 44.0 vs 49.5, p=0.035. Significantly fewer infants received postnatal steroids for BPD, 2.9% vs 7.9%, p=0.008.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP initiated in the delivery room with early surfactant in ELBW infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. Earlier we found that 100% of infants of 23 weeks gestation required intubation in the DR, and decided that such infants would unlikely be successfully treated with CPAP alone.[15] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[16]

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our trial differs from the recently reported trial of Morley et al[10-15] in that we randomized all eligible ELBW infants irrespective of whether they demonstrated spontaneous breathing and enough respiratory distress to warrant intervention. We also included infants of 24 weeks gestation and compared the CPAP and a protocol driven limited ventilator strategy with infants who were to receive surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold for intubation and the initiation of mechanical ventilation.[6,7] We believed that testing this complete approach would provide a more relevant result as units currently using early CPAP tend to have a higher threshold for intubation.

Formatted: Font: 12 pt, Superscript

We prospectively identified safety outcomes that we chose to follow as investigators. These included: the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H_2O compared to the use of early surfactant.

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO_2 target range. While the study was not powered to detect an interaction between the 2 interventions, we prospectively agreed to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was associated with a non-significant decrease in death by 36 weeks PMA or BPD as defined by the need for oxygen at 36 weeks from 54.1% to 48.7%. We also noted a significant 8.2% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.2 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal steroids and a reduction in BPD in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Comment [rng3]: Reference physiologic definition

Conclusions:

Compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth, infants between 24 and 27 6/7~~ths~~ weeks gestation assigned to treatment with CPAP as used in this trial have a non significant reduction in the incidence of death or BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse neonatal outcome. Early CPAP is associated with a significant reduction in mortality in the most

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

immature infants. CPAP as used in this trial is an effective evidence-based alternative to intubation and surfactant for very preterm infants.

Dear Neil, I read through the manuscript and thoroughly enjoyed seeing all of your hard work come to fruition. Congrats!!!!!! I have the advantage or disadvantage of having not seen this data before and of having not heard y'all talk about it before. So, I sort of consider my comments "fresh eyes".... someone who knows the protocol but hasn't dealt with it in awhile. I think my main comment would be that I would change the "surfactant" group name to "Early Intubation" or "Intubation" (to save words) or something like that. As I read the manuscript.... it seems like you are putting down the use of surfactant.... but what you are really trying to say is that it isn't beneficial to intubate these kids early... but if you do finally intubate them then give surfactant. By changing the group name I think you will avoid this impression. I also found some typos and other details. I had a few suggestions about how to reword things to make it clearer.

I had received an invitation to the call this afternoon and listened in for awhile, but needed to get off to see babies. I would agree that the NEJM will not allow you to include the strata stuff in the abstract. They also won't let you use ANY abbreviations. Thanks for the opportunity to review. I will try and look at Wally's manuscript as well. Sincerely, Brenda Morris

Early CPAP versus Surfactant in Very Preterm Infants: The SUPPORT Trial

NEIL, do you want to call them the Surfactant group or the "Early Intubation group (EI)"???? Looks like you are picking on surfactant when surfactant may be beneficial, but the intubation and ventilation is probably the culprit???? Was the decrease in deaths due to better survival in the babies who were not intubated??? I would assume this, but it might help your conclusion to be able to show that.

Acknowledgements (I sent several questions regarding the boilerplate to Stephanie for clarification with Wally's paper)

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilation strategy. Infants randomized to surfactant were intubated and received surfactant within 60 min minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 ??? ok to use abbreviation without spelling it out previously???? while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was non-significantly reduced in the CPAP group compared to the surfactant group, (48.7% vs 54.1%, RR 0.91, 95% CI 0.83, 1.01, p=0.072) when adjusted for gestational age, center and familial clustering. More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.03).

Conclusions: The use of CPAP is an effective evidence based alternative to intubation and surfactant in preterm infants.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[12] Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI). [3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with RDS .[456] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP.[789]

The recent COIN trial randomized 610 infants from 25 0/7 to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[10] This study did not compare early CPAP to the early administration of surfactant~~, and~~ as the surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analysis[4] ???REFERENCE????, and a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with a non significant decrease in death or BPD at 36 weeks.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The SUPPORT Trial was designed to compare early CPAP to early surfactant for the most preterm infants. The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a protocol driven limited ventilator strategy in infants of 24 to 27 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design. The results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation. Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Infants were also randomized to a prospective comparison using purpose altered oximeters of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen. ~~using purpose-altered oximeters.~~

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

~~The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a protocol driven limited ventilator strategy in infants of 24 to 27 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.~~

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a ~~randomizing~~ participating center, for whom a decision had been made to provide full resuscitation, and parental consent had been obtained. The infants were randomized within each center to two gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm – NEIL, As a person who knows about this trial but hasn't seen any of the results or been in on a discussion recently..... I had a hard time deciphering this paragraph. It wasn't clear that you were providing CPAP preferentially. I rearranged the sentences a bit. Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used for the delivery room administration of CPAP +5 as soon as possible after birth. CPAP was continued until admission to the NICU. CPAP infants were not to be intubated exclusively for surfactant administration in the DR. Intubation was to be performed only for the standard NRP indications.[11] CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. CPAP or ventilation with PEEP both at a recommended 5 cm H_2O was utilized if the infant required positive pressure during resuscitation. ~~CPAP was continued until admission to the NICU. CPAP infants were not to be intubated exclusively for surfactant administration in the DR, and CPAP infants who required~~

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

~~intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.~~[12]

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 ≥ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life the infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean airway pressure (MAP) < 10 cm H2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable~~, and~~ without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations CPAP infants were subsequently extubated ~~treated~~ using NICU specific standard practice. You could also say, "After 2 failed extubations, CPAP infants were subsequently extubated using center specific standard practice."

~~**Surfactant**~~ **Early Intubation Arm**: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30, aAn FiO2 ≤ 35 with a SpO2 ≥88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate ≤ 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

hemodynamically stable without evidence of clinically significant PDA. ~~Once extubated~~ ~~Surfactant~~Early intubation infants were treated using NICU standard practice after extubation.

For both groups intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery. These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. ~~For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.~~

~~Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.~~

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN baseline ~~occurrence~~ data. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment group as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition ~~after discharge and before follow-up~~prior to follow-up. This resulted in a sample size of 1310 infants. This sample size was not powered for an interaction effect between the 2 factorial arms.

Neil, This paragraph really didn't make much sense. Attempted to rework it. There was a prospective decision to also evaluate the occurrence of BPD using the "~~P~~physiologic

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

d~~D~~efinition" as defined by Walsh, et al (REFERNCE) as ~~which assigned the diagnosis of BPD to~~ any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support, ~~but~~ or failed~~required demonstration of oxygen dependence by~~ an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks. [1314]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks PMA without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. Continuous outcomes were analyzed using mixed effects linear models. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering (is this due to twins???). A two-sided P value of less than 0.05 was considered statistically significant.

An independent data safety monitoring committee reviewed the interim safety and efficacy results~~, including those concerning adverse outcomes,~~ four times. Lan-DeMets spending functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The study was approved by Human Subjects Committees at all sites and RTI International, the NRN data center. Parental consent for participation in the trial was required before deliveryenrollment. (You could actually enroll them after delivery!)

Results:

There were 1,316 infants enrolled from Feb 2005 through Feb 2009. Enrollment was temporarily suspended from November 2005 until February 2006 by the DSMB because of concerns regarding the oximetry data; no protocol changes were made. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, or race between the 2 treatment groups (Table 1).

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants. The Surfactant Early Intubation group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant. Surfactant, was given to 14.1% of the CPAP versus 51.4% of the surfactant early intubation group; 67.1% of the CPAP infants received surfactant in the delivery room or NICU, compared to 98.9% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34.4% of CPAP infants compared with 93.4% of surfactant infants, $p<0.001$, Table 2. How many of the CPAP infants never required intubation? I don't think you ever state this.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post menstrual age was non-significantly reduced for the CPAP group compared with the Surfactant early intubation group, 48.7% versus 54.1%, (RR 0.91, 05% CI 0.83, 1.01, p=0.072)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

when adjusted for gestational age, center and familial clustering as pre-specified. Death during the hospitalization was 3.2% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata, (23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.034), Table 4. Overall, there was a non-significant reduction in the occurrence of BPD at 36 weeks based on the use of supplemental oxygen, from 40.2% for the CPAP arm to 44.3% for the Surfactant arm,(RR 0.94, 95% CI 0.82, 1.06). Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39.2% vs. 40.6%, RR 0.99, 95% CI 0.87, 1.14). Death or Physiologic BPD at 36 weeks in the CPAP group was 47.8% vs. 51.0% for the Surfactant group, (RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room, length of stay, days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but 2 infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who required intubation during their nursery course (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (7.2 % vs 13.2%, p<0.001).

Strata Results: 24 – 25 weeks Gestation

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

CPAP infants had a significantly lower mortality while hospitalized 23.9% vs. 32.1%. Causes of death are reported in Table 5. There was a significantly higher exposure to postnatal steroids for BPD, 20.5% vs. 13.0%, p=0.023 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata. The incidence of retinopathy of prematurity ~~using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group~~[15] or need for surgical intervention for ROP was non-significantly reduced in the CPAP compared to the surfactant infants, (23.3% vs. 31.4%, RR=0.75, 95% CI 0.54, 1.05).

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups, 10.8% vs 10.2%. The CPAP infants required fewer days of oxygen, 44.0 vs 49.5, p=0.035. Significantly fewer infants received postnatal steroids for BPD, 2.9% vs 7.9%, p=0.008.

Neil, It looks like the days of mechanical ventilation is based only on the babies who were intubated. Shouldn't it be based on all babies randomized to the group????? That should show a much shorter duration in the CPAP group.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP intitiated in the delivery room with early surfactant in ELBW infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. Earlier we found that 100% of infants of 23 weeks gestation required intubation in

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

the DR, and decided that such infants would unlikely be successfully treated with CPAP alone.[16] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[17]

Our trial differs from the recently reported COIN trial[10~~10~~~~15~~] in that we randomized all eligible ELBW infants irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven limited ventilator strategy with infants who were to receive surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold approach for intubation and the initiation of mechanical ventilation.[6,7] We believed that testing this complete approach would provide a more relevant result as ~~units~~ practitioners currently using early CPAP tend to have a higher threshold for intubation.

Formatted: Font: 12 pt, Superscript

We prospectively identified safety outcomes that we chose to follow as investigators. These included; the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H2O compared to ~~the use of early surfactant~~early intubation and surfactant.

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we prospectively agreed to

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months. ~~and t~~These results will be presented after all survivors have been assessed.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was associated with a non-significant decrease in death by 36 weeks PMA or BPD as defined by the need for oxygen at 36 weeks from 54.1% to 48.7%. We also noted a significant 8.2% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.2 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal steroids, and a reduction in BPD in the overall CPAP group ~~without any increase in adverse neonatal outcomes~~ represents a substantial clinical benefit compared with ~~the initial use of early surfactant~~early intubation and surfactant therapy.

Conclusions:

Compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth, infants between 24 and 27 6/7ths weeks gestation assigned to treatment

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

with CPAP and a strategy of limited ventilation have a non significant reduction in the incidence of death or BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse neonatal outcome. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of early CPAP in such infants is an effective ~~evidence-based~~ alternative to intubation and surfactant.

Acknowledgements (I sent several questions regarding the boilerplate to Stephanie for clarification with Wally's paper)

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilation strategy. Infants randomized to surfactant were intubated and received surfactant within 60 minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was non-significantly reduced in the CPAP group compared to the surfactant group, (48.7% vs. 54.1%, RR 0.91, 95% CI 0.83, 1.01, p=0.072 when adjusted for gestational age, center and familial clustering. More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (23.9% vs. 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.03).

Conclusions: The use of CPAP is an effective evidence-based alternative to intubation and surfactant in preterm infants.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[12] Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI).[3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with RDS .[456] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP.[789]

The recent COIN trial randomized 610 infants from 25 0/7 to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H_20. CPAP infants were intubated if they met failure criteria.[10] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analysis**Error! Bookmark not defined.**. A reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006). The primary outcome of death or BPD at 36 weeks showed a non-significant difference.

The SUPPORT Trial was designed to compare early CPAP to early surfactant for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design. The results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters.

The primary hypothesis of this trial was that, relative to infants managed with prophylactic/early surfactant and conventional ventilation, the use of early CPAP and a protocol driven strategy of limited ventilation in infants of 24 to 27 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a randomizing center, for whom a decision had been made to provide full resuscitation, and parental consent had been obtained. The infants were

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

randomized within each center to two gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used for the delivery room administration of CPAP. CPAP or ventilation with PEEP, both at a recommended 5 cm H_2O, was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU. CPAP infants were not to be intubated exclusively for surfactant administration in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.[11]

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life, infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a $PaCO_2$ < 65 torr with a pH > 7.20, an SpO_2 > 88% with an FiO_2 < 50%, a mean airway pressure (MAP) < 10 cm H_2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations, CPAP infants were treated using NICU standard practice.

Surfactant Arm: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2 < 50$ torr and pH > 7.30, $FiO_2 \leq .35$ with a $SpO_2 \geq 88\%$, a MAP < 8 cm H_2O, ventilator rate $\leq$ 20 bpm, an amplitude < 2X MAP if on HFV, and hemodynamically stable without evidence of clinically significant PDA. Once extubated, Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN baseline occurrence data (BPD 67%, NDI 61%). We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not powered for an interaction effect between the 2 factorial arms.

There was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which assigned the diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support, but required demonstration of oxygen dependence by an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks. [1213]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks PMA without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. Continuous outcomes were analyzed using mixed effects linear models. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering. A two-sided P value of less than 0.05 was considered statistically significant.

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included

death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

The study was approved by Human Subjects Committees at all sites and RTI, the NRN data center. Parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled from Feb 2005 through Feb 2009. Enrollment was temporarily suspended from November 2005 until February 2006 by the DSMB because of concerns regarding the oximetry data; no protocol changes were made. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, or race between the 2 treatment groups (Table 1).

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant. Surfactant, was given to 14.1% of the CPAP versus 51.4% of the surfactant group; 67.1% of the CPAP infants received surfactant in the delivery room or NICU, compared to 98.9% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34.4% of CPAP infants compared with 93.4% of surfactant infants, $p<0.001$, Table 2.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post menstrual age was non-significantly reduced for the CPAP group compared with the Surfactant group, 48.7% versus 54.1%, (RR 0.91, 95% CI 0.83, 1.01, $p=0.072$) when adjusted for

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

gestational age, center and familial clustering as pre-specified. Death during the hospitalization was 3.2% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata, 23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.034, Table 4. Overall, there was a non-significant reduction in the occurrence of BPD based on the use of supplemental oxygen, from 40.2% for the CPAP arm to 44.3% for the Surfactant arm, (RR 0.94, 95% CI 0.82, 1.06). Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39.2% vs. 40.6%, RR 0.99, 95% CI 0.87, 1.14). Death or Physiologic BPD at 36 weeks in the CPAP group was 47.8% vs. 51.0% for the Surfactant group, (RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room, length of stay, days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but 2 infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who required intubation during their nursery course (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (7.2 % vs 13.2%, p<0.001).

Strata Results: 24 – 25 weeks Gestation

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

CPAP infants had a significantly lower mortality while hospitalized 23.9% vs. 32.1%. Causes of death are reported in Table 5. There was a significantly higher exposure to postnatal steroids for BPD, 20.5% vs. 13.0%, p=0.023 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata. The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[14] or need for surgical intervention for ROP was non-significantly reduced in the CPAP compared to the surfactant infants, (23.3% vs. 31.4%, RR=0.75, 95% CI 0.54, 1.05).

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups, 10.8% vs 10.2%. The CPAP infants required fewer days of oxygen, 44.0 vs 49.5, p=0.035. Significantly fewer infants received postnatal steroids for BPD, 2.9% vs 7.9%, p=0.008.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP initiated in the delivery room with early surfactant in ELBW infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. Earlier we found that 100% of infants of 23 weeks gestation required intubation in the DR, and decided that such infants would unlikely be successfully treated with CPAP alone.[15] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[16]

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our trial differs from the recently reported COIN trial[10] in that we randomized all eligible ELBW infants irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven limited ventilator strategy with infants who were to receive surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold for intubation and the initiation of mechanical ventilation.[6,7] We believed that testing this complete approach would provide a more relevant result as units currently using early CPAP tend to have a higher threshold for intubation.

We prospectively identified safety outcomes that we chose to follow as investigators. These included: the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H_2O compared to the use of early surfactant.

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO_2 target range. While the study was not powered to detect an interaction between the 2 interventions, we prospectively agreed to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was associated with a non-significant decrease in death by 36 weeks PMA or BPD as defined by the need for oxygen at 36 weeks from 54.1% to 48.7%. We also noted a significant 8.2% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.2 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal steroids and a reduction in BPD in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Conclusions:

Compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth, infants between 24 and 27 6/7ths weeks gestation assigned to treatment with CPAP and a strategy of limited ventilation have a non significant reduction in the incidence of death or BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse neonatal outcome. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

The p-values in Table 1 looking at whether randomization resulted in balance between treatments in terms of demographics are unadjusted because we are not looking at outcomes. However, if we think it makes more sense to make them adjusted I can do that.

All p-values for primary and secondary outcomes are adjusted. The only other unadjusted p-value is in the COD table. If we need an adjusted p-value I can produce one.

The reason that standard errors are presented instead of standard deviations in the tables with the adjusted tests is that the means in that table are adjusted for covariates. Standard errors give an estimate of how sure we are of our estimate of the adjusted mean. Another way we could go is to present CIs for the adjusted means.

Hi Marie
I had asked some of these questions earlier -
Why do we use unadjusted and adjusted p values. I assume that we would use adjusted for all primary and secondaries and unadjusted for the others - Is this what you have done??
Why do we flip between SD for gestation and birth weight and SEM for others??
Thanks
Neil

Abstract:
a) I suggest expand SUPPORT in Methods Section and BPD in Results

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

section. BPD already Done. SUPPORT not done
b) could you add how many of the infants in CPAP group subsequently required surfactant? I believe data is in Table 1. Also, was outcome know for all infants? In the abstract?
c) If you are tight for space in abstract, I suggest leave out "familial clustering" in Results and "evidence based" in the Conclusion No Need.

Introduction:
a) please clarify the primary outcome of COIN trial for ease for the NEJM reader Please look at this sentence
b) I would move the SUPPORT study hypothesis to the end of the Introduction, before Methods

Methods
a) I suggest you take out the "purpose altered oximeters" and just say there was the oximeters arm--as you have done later. Why open a Pandora's box?
I agree, but did not do this.
b) Substitute "NRN center" rather than "randomizing center" Not done
c) Under sample size---can you please provide the anticipated event rate in the early CPAP arm? We took these out for space a while ago for space, just saying we used 2000 baseline data.
d) can you clarify what the primary outcome is here (in abstract it says death or BPD, while here it appears to be death or disability--to me death or disability was a secondary outcome). Seems clear to me.
e) How was attrition rate of 17% arrived at---I think it is average loss to follow up in our FU studies---maybe you can state that? We asked Ken !
d) Is PHY BPD a secondary outcome? I wonder if you can make the description of PHY BPD definition a little clearer---maybe "step-wise oxygen-reduction to room air challenge among infants requiring > 30% oxygen without an assistance in ventilation" or some such wording. This came from Fanaroff.
e) expand PMA and clarify data center at RTI International, Research Triangle Park, NC and DSMC in caps If RTI did not ask to expand it, I would not take the space.

Results
a) for the CPAP paper do you really need to say Enrollment was halted for oxygen arm etc etc? I suggest leaving it out Your call.
b) Table 1: were any other maternal variables evaluated---mode of delivery, hypertension/PET? This is a study that might be influenced by perinatal variables other than ANCS. I suggest GA be shown in completed weeks and P values to 2 decimal points only in all Tables.
c) Table 2: I am not sure I follow why unadjusted P values are given for demographic (Table 1) but adjusted for Table 2.
d) Delivery room variables, Table 4 is cited in the Results section before Table 3---maybe you can change the Table order?
e) Table 3: Why was SEM used here rather than SD? Also, suggest expand Medical and surgical NEC. PDA, IVH--preferably ICH, in footnote
f) Since the study involved 24 to 28 wk infants, why show only lower strata in Table 4????
g) Is Table 5 necessary? Again, why is P value here unadjusted?
h) Was center not a variable for adjustment or did I miss something? I am not doing anything to the tables without direct consultation.

Discussion

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

a) I am not sure I understand "higher threshold approach for intubation" Can this be clarified? I took out 'approach'.
b) can you speculate why the overall outcome was not different in the 2 groups
c) Should any weaknesses be mentioned--

I know you are restrained by word count, but I believe expanding the discussion might help

Hope this helps
All the best
Seetha

Thanks for the heads up!

DSMC wants the death information shared with the other DSMCs. This is in progress.

Rose

No but I can.
Also: we have an issue: junior colleague of Neil Was speaking about SUPPORT results at another meeting Quite openly.
We spoke to Neil, and he said he would Take care of it. Don't know if we need to do more?
Also: was there any issue from DSMC? I was waiting to hear Before sharing with our faculty.

A couple of suggestions highlighted In turquoise.
Biggest: I do not believe that NEJM will allow statements Like non significant reduction in BPD: it is Not different. Steering committee was very clear about this Yet the language remains.

Here is the "final" CPAP vs Surf paper
It fits NEJM and incorporates all suggestions although some were opposite so we made some choices.
Please review
Wally can you make sure our definitions for BPD etc are identical??
Thanks
I would like to get these submitted
Please share with me your thoughts
Be well
Neil

Acknowledgements (I sent several questions regarding the boilerplate to Stephanie for clarification with Wally's paper)

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Running head: Early CPAP versus Surfactant and outcomes of prematurity

Key words: CPAP, bronchopulmonary dysplasia, extremely low birth weight infant, neonatal mortality, surfactant

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilation strategy. Infants randomized to surfactant were intubated and received surfactant within 60 ~~min~~ minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was non-significantly reduced in the CPAP group compared to the surfactant group, (48.7% vs 54.1%, RR 0.91, 95% CI 0.83, 1.01, p=0.072 when adjusted for gestational age, center and familial clustering. More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.03).

Conclusions: The use of CPAP -is an effective **evidence--based** alternative to intubation and surfactant in preterm infants.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[12] Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI).[3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with RDS .[456] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP.[789]

The recent COIN trial randomized 610 infants from 25 0/7 -to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H_20. CPAP infants were intubated if they met failure criteria.[10] In [redacted] surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta-analysis**Error! Bookmark not defined.**[7] ~~and a~~ A **reduction in** death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with a non significant decrease in death or BPD at 36 weeks was also noted in that study.

The SUPPORT Trial was designed to compare early CPAP to early surfactant for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

exposure to oxygen using a factorial design. The results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters.

The primary hypothesis of this trial was that, relative to infants managed with prophylactic/early surfactant and conventional ventilation, ~~that~~ the use of early CPAP and a protocol driven limited ventilator strategy in infants of 24 to 27 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a randomizing center, for whom a decision had been made to provide full resuscitation, and parental consent had been obtained. The infants were randomized within each center to two gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used for the delivery room administration of CPAP. CPAP or ventilation with PEEP, both at a recommended 5 cm H_2O, was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU. CPAP infants were not to be intubated exclusively for surfactant administration in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.[11]

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life, infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a $PaCO_2$ < 65 torr with a pH > 7.20, an SpO_2 > 88% with an FiO_2 < 50%, a mean airway pressure (MAP) < 10 cm H_2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations, CPAP infants were treated using NICU standard practice.

Surfactant Arm: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30, ~~AAnn~~ $FiO_2 \leq .35$ with a $SpO_2 \geq 88\%$, a ~~mean airway pressure (~~MAP~~)~~ < 8 cm H_2O, ventilator rate ≤ 20 bpm, an amplitude < 2X MAP if on ~~high frequency ventilation (~~HFV~~)~~, and hemodynamically stable without evidence of clinically significant PDA. Once extubated, Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN baseline occurrence data. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after

discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not powered for an interaction effect between the 2 factorial arms.

There was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which assigned the diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support, but required demonstration of oxygen dependence by an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks. [12,13]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks PMA without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. Continuous outcomes were analyzed using mixed effects linear models. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering. A two-sided P value of less than 0.05 was considered statistically significant.

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included

death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

The study was approved by Human Subjects Committees at all sites and RTI, the NRN data center. Parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled from Feb 2005 through Feb 2009. Enrollment was temporarily suspended from November 2005 until February 2006 by the DSMB because of concerns regarding the oximetry data; no protocol changes were made. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, or race between the 2 treatment groups (Table 1).

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant. Surfactant was given to 14.1% of the CPAP versus 51.4% of the surfactant group; 67.1% of the CPAP infants received surfactant in the delivery room or NICU, compared to 98.9% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34.4% of CPAP infants compared with 93.4% of surfactant infants, $p<0.001$, Table 2.

Formatted: Strikethrough, Highlight

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post menstrual age was non-significantly reduced for the CPAP group compared with the Surfactant group, 48.7% versus 54.1%, (RR 0.91, 95% CI 0.83, 1.01, p=0.072) when adjusted for

gestational age, center and familial clustering as pre-specified. Death during the hospitalization was 3.2% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata, 23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.034, Table 4. Overall, [redacted] of supplemental oxygen, from 40.2% for the CPAP arm to 44.3% for the Surfactant arm, (-RR 0.94, 95% CI 0.82, 1.06). Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39.2% vs. 40.6%, RR 0.99, 95% CI 0.87, 1.14). Death or Physiologic BPD at 36 weeks in the CPAP group was 47.8% vs. 51.0% for the Surfactant group, (RR 0.95, 95% CI 0.85, 1.05).

Comment [mw1]: Is this backwards? Control grp (surfactant is 44.3% which was lower in the CPAP 40.2%.
I do not think that you can say it was reduced: I think you can say it was the same.
Have we also looked at 40 wks? Ballard's group has found that 40 wks may be more predictive.

There were no significant differences overall for death in the delivery room, length of stay, days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but 2 infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who required intubation during their nursery course (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (7.2 % vs 13.2%, p<0.001).

Strata Results: 24 – 25 weeks Gestation

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

CPAP infants had a significantly lower mortality while hospitalized 23.9% vs. 32.1%. Causes of death are reported in Table 5. There was a significantly higher exposure to postnatal steroids for BPD, 20.5% vs. 13.0%, p=0.023 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata. The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[14] or need for surgical intervention for ROP was non-significantly reduced in the CPAP compared to the surfactant infants, (23.3% vs. 31.4%, RR=0.75, 95% CI 0.54, 1.05).

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups, 10.8% vs 10.2%. The CPAP infants required fewer days of oxygen, 44.0 vs 49.5, p=0.035. Significantly fewer infants received postnatal steroids for BPD, 2.9% vs 7.9%, p=0.008.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP initiated in the delivery room with early surfactant in ELBW infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. Earlier we found that 100% of infants of 23 weeks gestation required intubation in the DR, and decided that such infants would unlikely be successfully treated with CPAP alone.[15] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[16]

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our trial differs from the recently reported COIN trial[10] in that we randomized all eligible ELBW infants irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven limited ventilator strategy with infants who were to receive surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold approach for intubation and the initiation of mechanical ventilation.[6,7] We believed that testing this complete approach would provide a more relevant result as units currently using early CPAP tend to have a higher threshold for intubation.

We prospectively identified safety outcomes that we chose to follow as investigators. These included: the need for [redacted] compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H_2O compared to the use of early surfactant.

Formatted: Highlight

Formatted: Subscript, Highlight

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO_2 target range. While the study was not powered to detect an interaction between the 2 interventions, we prospectively agreed to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Formatted: Subscript, Highlight

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was associated with a non-significant decrease in death by 36 weeks PMA or BPD as defined by the need for oxygen at 36 weeks from 54.1% to 48.7%. We also noted a significant 8.2% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.2 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal steroids and a reduction in BPD in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Formatted: Strikethrough, Highlight

Conclusions:

Compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth, infants between 24 and 27 6/7ths weeks gestation assigned to treatment with CPAP and a strategy of limited ventilation have a non significant reduction in the incidence of death or BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse neonatal outcome. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

Thanks Marie
Can you quickly provide the adjusted values for the Death Table (Table 5). I would leave the rest and use your explanation if queried
Thanks
Neil

Subject: Re: CPAP vs SURF
Date: Monday, November 16, 2009 2:02:06 PM

Hi Seetha
Many thanks for your detailed review. We will incorporate many of these that have not already been done. I will remove the mention of stopping, and the purpose built oximeters
Center was a variable for adjustment, many asked for the cause of death including another internal reviewer
We will try to get these al changed and the submit and let the reviewers have a say.
Thanks again
Neil

Hi Marie
I had asked some of these questions earlier -
Why do we use unadjusted and adjusted p values. I assume that we would use adjusted for all primary and secondaries and unadjusted for the others – Is this what you have done??
Why do we flip between SD for gestation and birth weight and SEM for others??
Thanks
Neil

Subject: FW: CPAP vs SURF

Here is what I have done and not done from Seetha's comments. You may want to do more.
wade

Abstract:
a) I suggest expand SUPPORT in Methods Section and BPD in Results section. BPD already Done. SUPPORT not done
b) could you add how many of the infants in CPAP group subsequently required surfactant? I believe data is in Table 1. Also, was outcome know for all infants? In the abstract?
c) If you are tight for space in abstract, I suggest leave out "familial clustering" in Results and "evidence based" in the Conclusion No Need.

Introduction:
a) please clarify the primary outcome of COIN trial for ease for the NEJM reader Please look at this sentence
b) I would move the SUPPORT study hypothesis to the end of the Introduction, before Methods

Methods
a) I suggest you take out the "purpose altered oximeters" and just say there was the oximeters arm--as you have done later. Why open a Pandora's box?
I agree, but did not do this.
b) Substitute "NRN center" rather than "randomizing center" Not done
c) Under sample size---can you please provide the anticipated event rate in the early CPAP arm? We took these out for space a while ago for space, just saying we used 2000 baseline data.
d) can you clarify what the primary outcome is here (in abstract it says death or BPD, while here it appears to be death or disability--to me death or disability was a secondary outcome). Seems clear to me.
e) How was attrition rate of 17% arrived at---I think it is average loss to follow up in our FU studies---maybe you can state that? We asked Ken !
d) Is PHY BPD a secondary outcome? I wonder if you can make the description of PHY BPD definition a little clearer---maybe "step-wise oxygen-reduction to room air challenge among infants requiring > 30% oxygen without an assistance in ventilation" or some such wording. This came from Fanaroff.
e) expand PMA and clarify data center at RTI International, Research Triangle Park, NC and DSMC in caps If RTI did not ask to expand it, I would not take the space.

Results
a) for the CPAP paper do you really need to say Enrollment was halted for oxygen arm etc etc? I suggest leaving it out Your call.
b) Table 1: were any other maternal variables evaluated---mode of delivery, hypertension/PET? This is a study that

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

might be influenced by perinatal variables other than ANCS. I suggest GA be shown in completed weeks and P values to 2 decimal points only in all Tables.
c) Table 2: I am not sure I follow why unadjusted P values are given for demographic (Table 1) but adjusted for Table 2.
d) Delivery room variables, Table 4 is cited in the Results section before Table 3---maybe you can change the Table order?
e) Table 3: Why was SEM used here rather than SD? Also, suggest expand Medical and surgical NEC. PDA, IVH--preferably ICH, in footnote
f) Since the study involved 24 to 28 wk infants, why show only lower strata in Table 4????
g) Is Table 5 necessary? Again, why is P value here unadjusted?
h) Was center not a variable for adjustment or did I miss something? I am not doing anything to the tables without direct consultation.

Discussion
a) I am not sure I understand "higher threshold approach for intubation" Can this be clarified? I took out 'approach'.
b) can you speculate why the overall outcome was not different in the 2 groups
c) Should any weaknesses be mentioned--

I know you are restrained by word count, but I believe expanding the discussion might help

Hope this helps
All the best
Seetha

Acknowledgements (I sent several questions regarding the boilerplate to Stephanie for clarification with Wally's paper)

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilation strategy. Infants randomized to surfactant were intubated and received surfactant within 60 min minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was non-significantly reduced in the CPAP group compared to the surfactant group, (48.7% vs 54.1%, RR 0.91, 95% CI 0.83, 1.01, p=0.072 when adjusted for gestational age, center and familial clustering. More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.03).

Conclusions: The use of CPAP is an effective evidence based alternative to intubation and surfactant in preterm infants.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[12] Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI).[3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with RDS .[456] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP.[789]

The recent COIN trial randomized 610 infants from 25 0/7 to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[10] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analysis**Error! Bookmark not defined.**[4], and a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with a non significant decrease in death or BPD at 36 weeks.

The SUPPORT Trial was designed to compare early CPAP to early surfactant for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

exposure to oxygen using a factorial design. The results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters.

The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a protocol driven limited ventilator strategy in infants of 24 to 27 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a randomizing center, for whom a decision had been made to provide full resuscitation, and parental consent had been obtained. The infants were randomized within each center to two gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used for the delivery room administration of CPAP. CPAP or ventilation with PEEP both at a recommended 5 cm H_2O was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU. CPAP infants were not to be intubated exclusively for surfactant administration in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.[11]

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean airway pressure (MAP) < 10 cm H2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations CPAP infants were treated using NICU standard practice.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Surfactant Arm: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30 An FiO2 ≤ 35 with a SpO2 ≥88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate ≤ 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable without evidence of clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN baseline occurrence data. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not powered for an interaction effect between the 2 factorial arms.

There was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which assigned the diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support, but required demonstration of oxygen dependence by an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks. [1213]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks PMA without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. Continuous outcomes were analyzed using mixed effects linear models. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering. A two-sided P value of less than 0.05 was considered statistically significant.

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included

death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

The study was approved by Human Subjects Committees at all sites and RTI, the NRN data center. Parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled from Feb 2005 through Feb 2009. Enrollment was temporarily suspended from November 2005 until February 2006 by the DSMB because of concerns regarding the oximetry data; no protocol changes were made. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, or race between the 2 treatment groups (Table 1).

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant. Surfactant, was given to 14.1% of the CPAP versus 51.4% of the surfactant group; 67.1% of the CPAP infants received surfactant in the delivery room or NICU, compared to 98.9% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34.4% of CPAP infants compared with 93.4% of surfactant infants, $p<0.001$, Table 2.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post menstrual age was non-significantly reduced for the CPAP group compared with the Surfactant group, 48.7% versus 54.1%, (RR 0.91, 05% CI 0.83, 1.01, $p=0.072$) when adjusted for

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

gestational age, center and familial clustering as pre-specified. Death during the hospitalization was 3.2% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata, 23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.034, Table 4. Overall, there was a non-significant reduction in the occurrence of BPD based on the use of supplemental oxygen, from 40.2% for the CPAP arm to 44.3% for the Surfactant arm,(RR 0.94, 95% CI 0.82, 1.06). Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39.2% vs. 40.6%, RR 0.99, 95% CI 0.87, 1.14). Death or Physiologic BPD at 36 weeks in the CPAP group was 47.8% vs. 51.0% for the Surfactant group, (RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room, length of stay, days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but 2 infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who required intubation during their nursery course (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (7.2 % vs 13.2%, p<0.001).

Strata Results: 24 – 25 weeks Gestation

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

CPAP infants had a significantly lower mortality while hospitalized 23.9% vs. 32.1%. Causes of death are reported in Table 5. There was a significantly higher exposure to postnatal steroids for BPD, 20.5% vs. 13.0%, p=0.023 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata. The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[14] or need for surgical intervention for ROP was non-significantly reduced in the CPAP compared to the surfactant infants, (23.3% vs. 31.4%, RR=0.75, 95% CI 0.54, 1.05).

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups, 10.8% vs 10.2%. The CPAP infants required fewer days of oxygen, 44.0 vs 49.5, p=0.035. Significantly fewer infants received postnatal steroids for BPD, 2.9% vs 7.9%, p=0.008.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP intitiated in the delivery room with early surfactant in ELBW infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. Earlier we found that 100% of infants of 23 weeks gestation required intubation in the DR, and decided that such infants would unlikely be successfully treated with CPAP alone.[15] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[16]

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our trial differs from the recently reported COIN trial[10~~15~~] in that we randomized all eligible ELBW infants irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven limited ventilator strategy with infants who were to receive surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold approach for intubation and the initiation of mechanical ventilation.[6,7] We believed that testing this complete approach would provide a more relevant result as units currently using early CPAP tend to have a higher threshold for intubation.

Formatted: Font: 12 pt, Superscript

We prospectively identified safety outcomes that we chose to follow as investigators. These included; the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H2O compared to the use of early surfactant.

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we prospectively agreed to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was associated with a non-significant decrease in death by 36 weeks PMA or BPD as defined by the need for oxygen at 36 weeks from 54.1% to 48.7%. We also noted a significant 8.2% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.2 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal steroids and a reduction in BPD in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Conclusions:

Compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth, infants between 24 and 27 6/7ths weeks gestation assigned to treatment with CPAP and a strategy of limited ventilation have a non significant reduction in the incidence of death or BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse neonatal outcome. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

Subject: ++++CONFIDENTIAL: CPAP vs SURF

Hi-
Here is the most recent draft of the CPAP/surfactant paper.

We will discuss on Monday's call.

Thanks for all the assistance

Rose

Here is the "final" CPAP vs Surf paper
It fits NEJM and incorporates all suggestions although some were opposite so we made some choices.
Please review
Wally can you make sure our definitions for BPD etc are identical??
Thanks
I would like to get these submitted
Please share with me your thoughts
Be well
Neil

Hi Neil: I just added a couple of edits to what Vaneeti
Suggested. My main concern is that I think you should say
BPD was not different as opposed to reduced but not statistically significant.
Talk to you soon.

Acknowledgements (I sent several questions regarding the boilerplate to Stephanie for clarification with Wally's paper)

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Running head: Early CPAP versus Surfactant and outcomes of prematurity

Key words: CPAP, bronchopulmonary dysplasia, extremely low birth weight infant, neonatal mortality, surfactant

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilation strategy. Infants randomized to surfactant were intubated and received surfactant within 60 ~~min~~ minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was non-significantly reduced in the CPAP group compared to the surfactant group, (48.7% vs 54.1%, RR 0.91, 95% CI 0.83, 1.01, p=0.072 when adjusted for gestational age, center and familial clustering. More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.03).

Conclusions: The use of CPAP -is an effective evidence-based alternative to intubation and surfactant in preterm infants.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[12] Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI).[3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with RDS .[456] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP.[789]

The recent COIN trial randomized 610 infants from 25 0/7 -to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H_20. CPAP infants were intubated if they met failure criteria.[10] In the COIN trial surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta-analysis**Error! Bookmark not defined.**, ~~and~~ ~~a~~ A reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with a non significant decrease in death or BPD at 36 weeks was also noted in that study.

The SUPPORT Trial was designed to compare early CPAP to early surfactant for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

exposure to oxygen using a factorial design. The results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters.

The primary hypothesis of this trial was that, relative to infants managed with prophylactic/early surfactant and conventional ventilation, ~~that~~ the use of early CPAP and a protocol driven limited ventilator strategy in infants of 24 to 27 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Formatted: Highlight

Formatted: Strikethrough, Highlight

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a randomizing center, for whom a decision had been made to provide full resuscitation, and parental consent had been obtained. The infants were randomized within each center to two gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used for the delivery room administration of CPAP. CPAP or ventilation with PEEP, both at a recommended 5 cm H_2O, was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU. CPAP infants were not to be intubated exclusively for surfactant administration in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.[11]

Formatted: Highlight
Formatted: Highlight

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life, infants were to receive surfactant.

Formatted: Highlight

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a $PaCO_2$ < 65 torr with a pH > 7.20, an SpO_2 > 88% with an FiO_2 < 50%, a mean airway pressure (MAP) < 10 cm H_2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations, CPAP infants were treated using NICU standard practice.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Surfactant Arm: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30, ~~AAnn~~ $FiO_2 \leq .35$ with a SpO_2 ≥88%, a ~~mean airway pressure~~ (MAP) < 8 cm H_2O, ventilator rate ≤ 20 bpm, an amplitude < 2X MAP if on ~~high frequency ventilation~~ (HFV), and hemodynamically stable without evidence of clinically significant PDA. Once extubated, Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN baseline occurrence data. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after

discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not powered for an interaction effect between the 2 factorial arms.

There was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which assigned the diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support, but required demonstration of oxygen dependence by an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks. [1213]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks PMA without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. Continuous outcomes were analyzed using mixed effects linear models. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering. A two-sided P value of less than 0.05 was considered statistically significant.

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

The study was approved by Human Subjects Committees at all sites and RTI, the NRN data center. Parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled from Feb 2005 through Feb 2009. Enrollment was temporarily suspended from November 2005 until February 2006 by the DSMB because of concerns regarding the oximetry data; no protocol changes were made. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, or race between the 2 treatment groups (Table 1).

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant. Surfactant was given to 14.1% of the CPAP versus 51.4% of the surfactant group; 67.1% of the CPAP infants received surfactant in the delivery room or NICU, compared to 98.9% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34.4% of CPAP infants compared with 93.4% of surfactant infants, $p<0.001$, Table 2.

Formatted: Strikethrough, Highlight

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post menstrual age was non-significantly reduced for the CPAP group compared with the Surfactant group, 48.7% versus 54.1%, (RR 0.91, 95% CI 0.83, 1.01, p=0.072) when adjusted for

Formatted: Highlight

gestational age, center and familial clustering as pre-specified. Death during the hospitalization was 3.2% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata, 23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.034, Table 4. Overall, there was no significant reduction in the occurrence of BPD in the use of supplemental oxygen, from 40.2% for the CPAP arm to 44.3% for the Surfactant arm, (-RR 0.94, 95% CI 0.82, 1.06). Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39.2% vs. 40.6%, RR 0.99, 95% CI 0.87, 1.14). Death or Physiologic BPD at 36 weeks in the CPAP group was 47.8% vs. 51.0% for the Surfactant group, (RR 0.95, 95% CI 0.85, 1.05).

Comment [mw1]: Is this backwards? Control grp (surfactant is 44.3% which was lower in the CPAP 40.2%.
I do not think that you can say it was reduced: I think you can say it was the same.
Have we also looked at 40 wks? Ballard's group has found that 40 wks may be more predictive.

There were no significant differences overall for death in the delivery room, length of stay, days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but 2 infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who required intubation during their nursery course (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (7.2 % vs 13.2%, p<0.001).

Strata Results: 24 – 25 weeks Gestation

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

CPAP infants had a significantly lower mortality while hospitalized 23.9% vs. 32.1%. Causes of death are reported in Table 5. There was a significantly higher exposure to postnatal steroids for BPD, 20.5% vs. 13.0%, p=0.023 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata. The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[14] or need for surgical intervention for ROP was non-significantly reduced in the CPAP compared to the surfactant infants, (23.3% vs. 31.4%, RR=0.75, 95% CI 0.54, 1.05).

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups, 10.8% vs 10.2%. The CPAP infants required fewer days of oxygen, 44.0 vs 49.5, p=0.035. Significantly fewer infants received postnatal steroids for BPD, 2.9% vs 7.9%, p=0.008.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP initiated in the delivery room with early surfactant in ELBW infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. Earlier we found that 100% of infants of 23 weeks gestation required intubation in the DR, and decided that such infants would unlikely be successfully treated with CPAP alone.[15] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[16]

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our trial differs from the recently reported COIN trial[10] in that we randomized all eligible ELBW infants irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven limited ventilator strategy with infants who were to receive surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold approach for intubation and the initiation of mechanical ventilation.[6,7] We believed that testing this complete approach would provide a more relevant result as units currently using early CPAP tend to have a higher threshold for intubation.

We prospectively identified safety outcomes that we chose to follow as investigators. These included: the need for cardiac compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H_2O compared to the use of early surfactant.

Formatted: Highlight

Formatted: Subscript, Highlight

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO_2 target range. While the study was not powered to detect an interaction between the 2 interventions, we prospectively agreed to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Formatted: Subscript, Highlight

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was associated with a non-significant decrease in death by 36 weeks PMA or BPD as defined by the need for oxygen at 36 weeks from 54.1% to 48.7%. We also noted a significant 8.2% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.2 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal steroids and a reduction in BPD in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Formatted: Strikethrough, Highlight

Conclusions:

Compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth, infants between 24 and 27 6/7ths weeks gestation assigned to treatment with CPAP and a strategy of limited ventilation have a non significant reduction in the incidence of death or BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse neonatal outcome. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

HI,,,great work Neil, Wally, and RTI for wrapping up this landmark work

here are Ron and my comments on the CPAP vs SURF latest manuscript.

our main concern is to be careful w/ the statement "The use of CPAP is an effective evidence based alternative to intubation and surfactant in preterm infants" we think that alluding to the protocol's use of cpap of +5 in the protocol, and the 'protocol-driven limited ventilator strategy' by saying "CPAP, used as described in the study protocol...' or something similar, will limit extrapolation of the study results by clinicians seeking to justify any cpap strategy for all tiny babies...and w/ COINs high mortality among the lower gestational age cohort started on cpap of +8 (13% vs 7.6% controls), we think that being specific about use of cpap as in the protocol in the conclusions is important.

there are other comments/suggestions as well, but the cautious approach to the conclusion is our biggest question.

RE: CPAP vs SURF

Hi Neil
Great to see you last week. Rose had asked me to be an "internal reviewer" for this paper. I will not be able to be on the conf call today (on my way to MLS PI meeting).
I congratulate you getting the paper written so well and so quickly. I have a few comments and am basing them on my experience with NEJM and Hypothermia RCT paper. Remember, when they are done with you, you won't recognize your paper---just kidding!

Abstract:
a) I suggest expand SUPPORT in Methods Section and BPD in Results section.
b) could you add how many of the infants in CPAP group subsequently required surfactant? I believe data is in Table 1. Also, was outcome know for all infants?
c) If you are tight for space in abstract, I suggest leave out "familial clustering" in Results and "evidence based" in the Conclusion

Introduction:
a) Expand COIN and maybe substitute "clinical center" for "unit"? also, please clarify the primary outcome of COIN trial for ease for the NEJM reader
b) I would move the SUPPORT study hypothesis to the end of the

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Introduction, before Methods

Methods
a) I suggest you take out the "purpose altered oximeters" and just say there was the oximeters arm--as you have done later. Why open a Pandora's box?
b) Substitute "NRN center" rather than "randomizing center"
c) Under sample size---can you please provide the anticipated event rate in the early CPAP arm?
d) can you clarify what the primary outcome is here (in abstract it says death or BPD, while here it appears to be death or disability--to me death or disability was a secondary outcome).
e) How was attrition rate of 17% arrived at---I think it is average loss to follow up in our FU studies---maybe you can state that?
d) Is PHY BPD a secondary outcome? I wonder if you can make the description of PHY BPD definition a little clearer---maybe "step-wise oxygen-reduction to room air challenge among infants requiring > 30% oxygen without an assistance in ventilation" or some such wording.
e) expand PMA and clarify data center at RTI International, Research Triangle Park, NC and DSMC in caps

Results
a) for the CPAP paper do you really need to say Enrollment was halted for oxygen arm etc etc? I suggest leaving it out
b) Table 1: were any other maternal variables evaluated---mode of delivery, hypertension/PET? This is a study that might be influenced by perinatal variables other than ANCS. I suggest GA be shown in completed weeks and P values to 2 decimal points only in all Tables.
c) Table 2: I am not sure I follow why unadjusted P values are given for demographic (Table 1) but adjusted for Table 2.
d) Delivery room variables, Table 4 is cited in the Results section before Table 3---maybe you can change the Table order?
e) Table 3: Why was SEM used here rather than SD? Also, suggest expand Medical and surgical NEC. PDA, IVH--preferably ICH, in footnote
f) Since the study involved 24 to 28 wk infants, why show only lower strata in Table 4????
g) Is Table 5 necessary? Again, why is P value here unadjusted?
h) Was center not a variable for adjustment or did I miss something?

Discussion
a) I am not sure I understand "higher threshold approach for intubation" Can this be clarified?
b) can you speculate why the overall outcome was not different in the 2 groups
c) Should any weaknesses be mentioned--

I know you are restrained by word count, but I believe expanding the discussion might help

Hope this helps
All the best
Seetha

Wally and Rose
Here is the "final" CPAP vs Surf paper
It fits NEJM and incorporates all suggestions although some were opposite
so we made some choices.
Please review
Wally can you make sure our definitions for BPD etc are identical??
Thanks
I would like to get these submitted
Please share with me your thoughts
Be well
Neil

Acknowledgements (I sent several questions regarding the boilerplate to Stephanie for clarification with Wally's paper)

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks gestation. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol-driven limited ventilation strategy. Infants randomized to surfactant were intubated and received surfactant within 60 ~~min~~ minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was non-significantly reduced in the CPAP group compared to the surfactant group, (48.7% vs 54.1%, RR 0.91, 95% CI 0.83, 1.01, p=0.072) when adjusted for gestational age, center and familial clustering. More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.03).

Conclusions: The use of CPAP as described in this protocol is an effective evidence based alternative to intubation and surfactant in preterm infants.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[12] Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants, and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI).[3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with RDS .[456] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP.[789]

The recent COIN trial randomized 610 infants from 25 0/7 to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age, but ~~and~~ had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[10] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analysis.**Error! Bookmark not defined.**~~4,~~ There was also a trend toward increased mortality among the youngest strata of infants (25 – 26 weeks) randomized to CPAP (13% vs. 7.6%), but for the whole study cohort, death or the need for oxygen at 28 days was reduced in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with no difference in the composite outcome death or BPD at 36 weeks.~~and a reduction in death or the need for~~

Comment [c1]: I think it is important to point out the distinct difference in cpap 8 vs. cpap 5, and if we are reporting the good effect in the youngest subgroup, it's fair to report the poor outcome in the youngest subgroup in COIN (that was exposed to cpap+8)....this also leads me to think that particulars about how cpap was used (+5 vs. +8, may lead to very different outcomes for the most fragile kids.

~~oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with a non significant decrease in death or BPD at 36 weeks.~~

The SUPPORT Trial was designed to compare early CPAP to early surfactant for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design. The results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol-driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purposely-altered oximeters.

The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation, ~~that the~~ use of early CPAP and a protocol-driven limited ventilator strategy in infants of 24 to 27 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a randomizing center, for whom a decision had been made to provide full resuscitation, and parental consent had been obtained. The infants were randomized within each center to two gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used for the delivery room administration of CPAP. CPAP or ventilation with PEEP both at a recommended 5 cm H_2O was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU. CPAP infants were not to be intubated exclusively for surfactant administration in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.[11]

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

airway pressure (MAP) < 10 cm H2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations CPAP infants were treated using NICU standard practice.

Surfactant Arm: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30 An FiO2 ≤ 35 with a SpO2 ≥88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate ≤ 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable without evidence of clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

baseline occurrence data. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not powered for an interaction effect between the 2 factorial arms.

There was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which assigned the diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support, but required demonstration of oxygen dependence by an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks. [12,13]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks post menstrual age (PMA) without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. Continuous outcomes were analyzed using mixed effects linear models. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering. A two-sided P value of less than 0.05 was considered statistically significant.

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

The study was approved by Human Subjects Committees at all sites and RTI, the NRN data center. Parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled from Feb 2005 through Feb 2009. Enrollment was temporarily suspended from November 2005 until February 2006 by the DSMB because of concerns regarding the oximetry data; no protocol changes were made. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, or race between the 2 treatment groups (Table 1).

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant. In the delivery room, ~~Surfactant~~surfactant~~,~~ was given to 14.1% of the CPAP versus 51.4% of the surfactant group; 67.1% of the CPAP infants received surfactant in the delivery room or NICU, compared to 98.9% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34.4% of CPAP infants compared with 93.4% of surfactant infants, $p<0.001$, Table 2.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post menstrual age was non-significantly reduced for the CPAP group compared with the Surfactant group, 48.7% versus 54.1%, (RR 0.91, 05% CI 0.83, 1.01, p=0.072) when adjusted for gestational age, center and familial clustering as pre-specified. Death during the hospitalization was 3.2% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata, 23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.034, Table 4. Overall, there was a non-significant reduction in the occurrence of BPD based on the use of supplemental oxygen, from 40.2% for the CPAP arm to 44.3% for the Surfactant arm,(RR 0.94, 95% CI 0.82, 1.06). Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39.2% vs. 40.6%, RR 0.99, 95% CI 0.87, 1.14). Death or Physiologic BPD at 36 weeks in the CPAP group was 47.8% vs. 51.0% for the Surfactant group, (RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room, length of stay, days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but 2 infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who required intubation during their nursery course (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (7.2 % vs 13.2%, p<0.001).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Strata Results: 24 – 25 weeks Gestation

CPAP infants had a significantly lower mortality while hospitalized 23.9% vs. 32.1%. Causes of death are reported in Table 5. There was a significantly higher exposure to postnatal steroids for BPD, 20.5% vs. 13.0%, p=0.023 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata. The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[14] or need for surgical intervention for ROP was non-significantly reduced in the CPAP compared to the surfactant infants, (23.3% vs. 31.4%, RR=0.75, 95% CI 0.54, 1.05).

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups, 10.8% vs 10.2%. The CPAP infants required fewer days of oxygen, 44.0 vs 49.5, p=0.035. Significantly fewer infants received postnatal steroids for BPD, 2.9% vs 7.9%, p=0.008.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP intitiated in the delivery room with early surfactant in ELBW infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. Earlier we found that 100% of infants of 23 weeks gestation required intubation in the DR, and decided that such infants would unlikely be successfully treated with CPAP alone.[15]

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[16]

Our trial differs from the recently reported COIN trial[10~~15~~] in that we randomized all eligible ELBW infants irrespective of whether they demonstrated spontaneous breathing and enough respiratory distress to warrant intervention~~,~~. We also included infants of 24 weeks gestation and compared the CPAP and a protocol-driven limited ventilator strategy with infants who were to receive surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold approach for intubation and the initiation of mechanical ventilation.[6,7] We believed that testing this complete approach would provide a more relevant result as units currently using early CPAP tend to have a higher threshold for intubation.

Formatted: Font: 12 pt, Superscript

Comment [c2]: Making this comment about the 'complete approach' I think impacts what you can say in the conclusion about cpap in a general way....I think saying the complete approach, including cpap of 5 in the DR and limited vent strategy is what's associated w/ benefit..not just 'cpap'

We prospectively identified safety outcomes that we chose to follow as investigators. These included; the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H2O compared to the use of early surfactant.

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we prospectively agreed to evaluate such interactions and none were found. Both arms of the study were adequately

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was associated with a non-significant decrease in death by 36 weeks PMA or BPD as defined by the need for oxygen at 36 weeks from 54.1% to 48.7%. We also noted a significant 8.2% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.2 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal steroids and a reduction in BPD in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Conclusions:

Compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth, infants between 24 and 27 6/7ths weeks gestation assigned to treatment with CPAP and a strategy of limited ventilation have a non significant reduction in the incidence of death or BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

in any adverse neonatal outcome. Early CPAP is associated with a significant reduction in mortality in the most immature infants. In such infants, ~~The~~ use of CPAP and a limited ventilation as described in this protocol ~~in such infants~~ is an effective evidence-based alternative to intubation and surfactant.

Comment [c3]: I think the paper will greatly influence practice....I think given the big difference between this and the COIN trial..and the mortality in the COIN trial in the youngest kids, that it's important to strongly say that the invertention that's an alternative is using the whole protocol definition, not just simply CPAP.

From: Das, Abhik
To: Brenda B Poindexter
Cc: Higgins, Rosemary (NIH/NICHD) [E]
Subject: statistical review of SUPPORT school age breathing outcomes
Date: Monday, November 16, 2009 11:42:49 AM

Brenda:

Here is what I alluded to on the call today.

1. Problems with sample size calculations:
    a. Attrition may not be uniform across the 4 treatment combination cells
    b. There will be at least two pair-wise comparisons; so significance level of 5% seems too liberal
    c. It is not clear whether only marginal analyses or comparison of all 4 groups to each other is contemplated. The latter has implications for both effect size and significance level
2. Analysis plan needs to consider covariate adjustments. Even though the data is from a randomized trial, deaths and attrition likely make the benefits of randomization (with respect to covariate imbalance) moot. So, careful attention needs to be paid a priori (to discourage 'fishing') to what covariates need adjustments (or clear criteria by which these will be selected).

Hope this helps.

Thanks

A couple of suggestions highlighted In turquoise.
Biggest: I do not believe that NEJM will allow statements
Like non significant reduction in BPD: it is
Not different. Steering committee was very clear about this
Yet the language remains.

Subject: CPAP vs SURF

Wally and Rose
Here is the "final" CPAP vs Surf paper
It fits NEJM and incorporates all suggestions although some were
opposite so we made some choices.
Please review
Wally can you make sure our definitions for BPD etc are identical??
Thanks
I would like to get these submitted
Please share with me your thoughts
Be well
Neil

Acknowledgements (I sent several questions regarding the boilerplate to Stephanie for clarification with Wally's paper)

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Running head: Early CPAP versus Surfactant and outcomes of prematurity

Key words: CPAP, bronchopulmonary dysplasia, extremely low birth weight infant, neonatal mortality, surfactant

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilation strategy. Infants randomized to surfactant were intubated and received surfactant within 60 ~~min~~ minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was non-significantly reduced in the CPAP group compared to the surfactant group, (48.7% vs 54.1%, RR 0.91, 95% CI 0.83, 1.01, p=0.072 when adjusted for gestational age, center and familial clustering. More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.03).

Conclusions: The use of CPAP ~~-~~is an effective evidence~~-~~based alternative to intubation and surfactant in preterm infants.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[12] Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI).[3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with RDS .[456] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP.[789]

The recent COIN trial randomized 610 infants from 25 0/7 -to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H_20. CPAP infants were intubated if they met failure criteria.[10] In the COIN Trial surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta-analysis**Error! Bookmark not defined.**, ~~and~~ ~~a~~ A reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with a non significant decrease in death or BPD at 36 weeks was also noted in that study.

The SUPPORT Trial was designed to compare early CPAP to early surfactant for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

exposure to oxygen using a factorial design. The results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters.

The primary hypothesis of this trial was that, relative to infants managed with prophylactic/early surfactant and conventional ventilation, ~~that~~ the use of early CPAP and a protocol driven limited ventilator strategy in infants of 24 to 27 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Formatted: Strikethrough, Highlight

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a randomizing center, for whom a decision had been made to provide full resuscitation, and parental consent had been obtained. The infants were randomized within each center to two gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used for the delivery room administration of CPAP. CPAP or ventilation with PEEP, both at a recommended 5 cm H_2O, was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU. CPAP infants were not to be intubated exclusively for surfactant administration in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.[11]

Formatted: Highlight
Formatted: Highlight

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life, infants were to receive surfactant.

Formatted: Highlight

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a $PaCO_2$ < 65 torr with a pH > 7.20, an SpO_2 > 88% with an FiO_2 < 50%, a mean airway pressure (MAP) < 10 cm H_2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations, CPAP infants were treated using NICU standard practice.

Surfactant Arm: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30, ~~AAnn~~ FiO_2 ≤ .35 with a SpO_2 ≥88%, a ~~mean airway pressure~~ (MAP) < 8 cm H_2O, ventilator rate ≤ 20 bpm, an amplitude < 2X MAP if on ~~high frequency ventilation~~ (HFV), and hemodynamically stable without evidence of clinically significant PDA. Once extubated, Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN baseline occurrence data. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after

discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not powered for an interaction effect between the 2 factorial arms.

There was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which assigned the diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support, but required demonstration of oxygen dependence by an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks. [12,13]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks PMA without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. Continuous outcomes were analyzed using mixed effects linear models. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering. A two-sided P value of less than 0.05 was considered statistically significant.

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included

death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

The study was approved by Human Subjects Committees at all sites and RTI, the NRN data center. Parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled from Feb 2005 through Feb 2009. Enrollment was temporarily suspended from November 2005 until February 2006 by the DSMB because of concerns regarding the oximetry data; no protocol changes were made. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, or race between the 2 treatment groups (Table 1).

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant. Surfactant was given to 14.1% of the CPAP versus 51.4% of the surfactant group; 67.1% of the CPAP infants received surfactant in the delivery room or NICU, compared to 98.9% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34.4% of CPAP infants compared with 93.4% of surfactant infants, $p<0.001$, Table 2.

Formatted: Strikethrough, Highlight

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post menstrual age was non-significantly reduced for the CPAP group compared with the Surfactant group, 48.7% versus 54.1%, (RR 0.91, 95% CI 0.83, 1.01, p=0.072) when adjusted for

Formatted: Highlight

gestational age, center and familial clustering as pre-specified. Death during the hospitalization was 3.2% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata, 23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.034, Table 4. Overall, [redacted] of supplemental oxygen, from 40.2% for the CPAP arm to 44.3% for the Surfactant arm, (-RR 0.94, 95% CI 0.82, 1.06). Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39.2% vs. 40.6%, RR 0.99, 95% CI 0.87, 1.14). Death or Physiologic BPD at 36 weeks in the CPAP group was 47.8% vs. 51.0% for the Surfactant group, (RR 0.95, 95% CI 0.85, 1.05).

Comment [mw1]: Is this backwards? Control grp (surfactant is 44.3% which was lower in the CPAP 40.2%.
I do not think that you can say it was reduced: I think you can say it was the same.
Have we also looked at 40 wks? Ballard's group has found that 40 wks may be more predictive.

There were no significant differences overall for death in the delivery room, length of stay, days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but 2 infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who required intubation during their nursery course (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (7.2 % vs 13.2%, p<0.001).

Strata Results: 24 – 25 weeks Gestation

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

CPAP infants had a significantly lower mortality while hospitalized 23.9% vs. 32.1%. Causes of death are reported in Table 5. There was a significantly higher exposure to postnatal steroids for BPD, 20.5% vs. 13.0%, p=0.023 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata. The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[14] or need for surgical intervention for ROP was non-significantly reduced in the CPAP compared to the surfactant infants, (23.3% vs. 31.4%, RR=0.75, 95% CI 0.54, 1.05).

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups, 10.8% vs 10.2%. The CPAP infants required fewer days of oxygen, 44.0 vs 49.5, p=0.035. Significantly fewer infants received postnatal steroids for BPD, 2.9% vs 7.9%, p=0.008.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP initiated in the delivery room with early surfactant in ELBW infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. Earlier we found that 100% of infants of 23 weeks gestation required intubation in the DR, and decided that such infants would unlikely be successfully treated with CPAP alone.[15] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[16]

Formatted: Highlight

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our trial differs from the recently reported COIN trial[10] in that we randomized all eligible ELBW infants irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven limited ventilator strategy with infants who were to receive surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold approach for intubation and the initiation of mechanical ventilation.[6,7] We believed that testing this complete approach would provide a more relevant result as units currently using early CPAP tend to have a higher threshold for intubation.

We prospectively identified safety outcomes that we chose to follow as investigators. These included: the need for cardiac compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H_2O compared to the use of early surfactant.

Formatted: Highlight

Formatted: Subscript, Highlight

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO_2 target range. While the study was not powered to detect an interaction between the 2 interventions, we prospectively agreed to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Formatted: Subscript, Highlight

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was associated with a non-significant decrease in death by 36 weeks PMA or BPD as defined by the need for oxygen at 36 weeks from 54.1% to 48.7%. We also noted a significant 8.2% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.2 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal steroids and a reduction in BPD in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Formatted: Strikethrough, Highlight

Conclusions:

Compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth, infants between 24 and 27 6/7ths weeks gestation assigned to treatment with CPAP and a strategy of limited ventilation have a non significant reduction in the incidence of death or BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse neonatal outcome. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

Hi Wally
Rose asked me to be internal reviewer and I won't be on call today, so here are my comments/suggestions. I congratulate you on the speed with which both you and Neil have done your respective manuscripts---you both now will hold the record for time from Data lock to Publication!

Abstract:
Results: since you do have RR and 95%CI in your Results section, maybe you don't need the P value

Methods:

a) The median actual saturation value---is this throughout the intervention period?
b) Explain how the 17% attrition was arrived at (see my comments to Neil)

Methods and/or Results

a) I wonder if you should give the citation for PHY BPD paper?
b) Table 1: Why are the N's in the this paper different from the N's in Neil's paper---are they not the same infants?
c) As mentioned re Neil's paper I wonder if other maternal characteristics should be included---PNC, Hypertension/PET, IUGR status that impact on frequency of RDS
d) Table 2: Missing data under each should be included in footnotes---then you could take off numerator /denominator and Tables will be less crowded
e) Table 2: Since this includes both primary and secondary outcomes, maybe bold the primary outcome?
f) Define Late onset sepsis---PVL is "cystic PVL"
g) Was center adjusted for---centers with more Black infants will have lower ROP
h) Figure !: This is excellent. I am intrigued by 698 who were eligible, consent not sought---even though personnel and equipment were available and the 66 for whom consent was obtained but not randomized---maybe add as footnote??? Footnotes are not counted anyway

Discussion:

a) excellent, suggest commenting on center differences if you find any.
b) How does our reduction of risk of ROP compare to Askie's?
c) Any perceived weaknesses of our trial—may as well say it (pre-emptive strike!)

Thanks for the opportunity to review. Beena is site PI from Wayne State for this and Neil's study

All the best
Seetha

Hi,

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Attached are the two papers in draft form for the SUPPORT Primary outcomes. As noted, there is an increase in death in the lower saturation group (20%) versus the higher saturation group (16%).

This information is confidential and a plan is in place for DSMC communication with ongoing trials of oxygen saturation. If you are contacted by any investigators from other trials or elsewhere, do not share this information. If necessary, refer them to me.

The plan for submission is as follows:

November 16 – 4 PM – call for Steering committee and authors to discuss papers. In the meantime, feel free to send comments to Neil and Wally. The call in number is:
866-675(b) (6) with passcode(b) (6)

If you are not going to be on the call, send comments in advance or designate someone to serve in your absence.

Immediately following the call, the manuscripts will be finalized for NICHD clearance and for submission to the New England Journal of Medicine.

Thanks in advance to everyone for all their hard work!!!
Rose

Subject NICHD Neonatal Research Network SUPPORT Trial ROP Adjudication Cases

Dear Drs. Wallace, Freedman, Hutcheson and Markowitz,

On behalf of Dr. Rose Higgins, Program Officer for the NICHD Neonatal Research Network, please find attached SUPPORT Trial cases requiring adjudication for ROP outcomes along with supporting documents to assist you with these cases to include:

- A section of the SUPPORT Trial study manual regarding the documentation of ophthalmological examinations for ROP and follow up eye outcomes
- Associated case report forms (data forms) used to collect ROP data (SUPP10 Form) and follow up eye outcomes (NF05 Form)

We would very much appreciate your response to these data by marking the appropriate check box per infant case and sending this data back to me by email or fax (contacts below) within the next 2 to 3 weeks.

Thank you in advance and please don't hesitate to contact me should you have any questions at all.
Kris

From a learning curve, figuring out what the forms showed and how to thinking about it, working together was probably very efficient and helpful (if they got it right).

On the other hand, it does not give us two independent scores which is a shame.

Did we have a 3rd adjudicator? If the 3rd agrees with the consensus, that would be fine.

If not, I would prefer to get another judgment.

Dear Drs. Wallace, Freedman, Hutcheson and Markowitz,

On behalf of Dr. Rose Higgins, Program Officer for the NICHD Neonatal Research Network, please find attached SUPPORT Trial cases requiring adjudication for ROP outcomes along with supporting documents to assist you with these cases to include:

- A section of the SUPPORT Trial study manual regarding the documentation of ophthalmological examinations for ROP and follow up eye outcomes
- Associated case report forms (data forms) used to collect ROP data (SUPP10 Form) and follow up eye outcomes (NF05 Form)

We would very much appreciate your response to these data by marking the appropriate check box per infant case and sending this data back to me by email or fax (contacts below) within the next 2 to 3 weeks.

Thank you in advance and please don't hesitate to contact me should you have any questions at all.

Subject: Re: CPAP vs SURF

If you want both papers to appear in the same issue of any jornal, we would need to proactively state this. Otherwise, the publications may appear at different times. If everyone is ok with this, that is fine. It would be ideal (perhaps too optimistic) to have them appear simultaneously in the literature.

Why would we give them an ultimatum?
I think both papers stand well enough alone and NEJM is NOT the only option
What to the rest of you think. I am sure Peds would take then both.
Neil

Hi Rose:

Marsha could not finish the manuscript today but Cassandra will do it on Monday AM.

One question: I was not going to put a table in the text but include it in the appendix as NEJM has table/figure limitation. I will have a statement in the paper saying cause of death did not differ. We can also put all data in the text. What do you think?

Wally

Wally and Rose
Here is the "final" CPAP vs Surf paper
It fits NEJM and incorporates all suggestions although some were opposite so we made some choices.
Please review
Wally can you make sure our definitions for BPD etc are identical??
Thanks
I would like to get these submitted
Please share with me your thoughts
Be well
Neil

Acknowledgements (I sent several questions regarding the boilerplate to Stephanie for clarification with Wally's paper)

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Running head: Early CPAP versus Surfactant and outcomes of prematurity

Key words: CPAP, bronchopulmonary dysplasia, extremely low birth weight infant, neonatal mortality, surfactant

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilation strategy. Infants randomized to surfactant were intubated and received surfactant within 60 min minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was non-significantly reduced in the CPAP group compared to the surfactant group, (48.7% vs 54.1%, RR 0.91, 95% CI 0.83, 1.01, p=0.072 when adjusted for gestational age, center and familial clustering. More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011) and fewer required intubation or post natal steroids for BPD, (p<.001). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.03).

Conclusions: The use of CPAP is an effective evidence based alternative to intubation and surfactant in preterm infants.

Introduction:

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[12] Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI).[3] There is now a growing body of evidence suggesting a benefit for early CPAP for preterm infants with RDS .[456] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following early CPAP.[789]

The recent COIN trial randomized 610 infants from 25 0/7 to 28 6/7 weeks gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[10] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analysis**Error! Bookmark not defined.**[4], and a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with a non significant decrease in death or BPD at 36 weeks.

The SUPPORT Trial was designed to compare early CPAP to early surfactant for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

exposure to oxygen using a factorial design. The results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324). This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters.

The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a protocol driven limited ventilator strategy in infants of 24 to 27 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born without known malformations at a randomizing center, for whom a decision had been made to provide full resuscitation, and parental consent had been obtained. The infants were randomized within each center to two gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used for the delivery room administration of CPAP. CPAP or ventilation with PEEP both at a recommended 5 cm H_2O was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU. CPAP infants were not to be intubated exclusively for surfactant administration in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications.[11]

NICU management: CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within 1 hour prior to intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean airway pressure (MAP) < 10 cm H2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations CPAP infants were treated using NICU standard practice.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Surfactant Arm: All infants were to be intubated in the delivery room and receive surfactant within 1 hour of life, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30 An FiO2 ≤ 35 with a SpO2 ≥88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate ≤ 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable without evidence of clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, with multiples randomized to the same arm.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months by 10%, based on year 2000 NRN baseline occurrence data. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not powered for an interaction effect between the 2 factorial arms.

There was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which assigned the diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support, but required demonstration of oxygen dependence by an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks. [1213]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each group who survived to 36 weeks PMA without BPD. Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. Continuous outcomes were analyzed using mixed effects linear models. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age strata, center and familial clustering. A two-sided P value of less than 0.05 was considered statistically significant.

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock or O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

death, pneumothorax, intraventricular hemorrhage and the need for chest compressions or epinephrine in the delivery room.

The study was approved by Human Subjects Committees at all sites and RTI, the NRN data center. Parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled from Feb 2005 through Feb 2009. Enrollment was temporarily suspended from November 2005 until February 2006 by the DSMB because of concerns regarding the oximetry data; no protocol changes were made. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, or race between the 2 treatment groups (Table 1).

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant. Surfactant, was given to 14.1% of the CPAP versus 51.4% of the surfactant group; 67.1% of the CPAP infants received surfactant in the delivery room or NICU, compared to 98.9% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34.4% of CPAP infants compared with 93.4% of surfactant infants, $p<0.001$, Table 2.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post menstrual age was non-significantly reduced for the CPAP group compared with the Surfactant group, 48.7% versus 54.1%, (RR 0.91, 05% CI 0.83, 1.01, $p=0.072$) when adjusted for

gestational age, center and familial clustering as pre-specified. Death during the hospitalization was 3.2% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata, 23.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.034, Table 4. Overall, there was a non-significant reduction in the occurrence of BPD based on the use of supplemental oxygen, from 40.2% for the CPAP arm to 44.3% for the Surfactant arm,(RR 0.94, 95% CI 0.82, 1.06). Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39.2% vs. 40.6%, RR 0.99, 95% CI 0.87, 1.14). Death or Physiologic BPD at 36 weeks in the CPAP group was 47.8% vs. 51.0% for the Surfactant group, (RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room, length of stay, days of oxygen for survivors, or discharge on oxygen (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All but 2 infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who required intubation during their nursery course (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants (7.2 % vs 13.2%, p<0.001).

Strata Results: 24 – 25 weeks Gestation

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

CPAP infants had a significantly lower mortality while hospitalized 23.9% vs. 32.1%. Causes of death are reported in Table 5. There was a significantly higher exposure to postnatal steroids for BPD, 20.5% vs. 13.0%, p=0.023 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata. The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[14] or need for surgical intervention for ROP was non-significantly reduced in the CPAP compared to the surfactant infants, (23.3% vs. 31.4%, RR=0.75, 95% CI 0.54, 1.05).

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups, 10.8% vs 10.2%. The CPAP infants required fewer days of oxygen, 44.0 vs 49.5, p=0.035. Significantly fewer infants received postnatal steroids for BPD, 2.9% vs 7.9%, p=0.008.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare CPAP intitiated in the delivery room with early surfactant in ELBW infants and the only prospective randomized trial comparing CPAP to any other intervention that enrolled infants of 24 weeks gestation. Earlier we found that 100% of infants of 23 weeks gestation required intubation in the DR, and decided that such infants would unlikely be successfully treated with CPAP alone.[15] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[16]

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our trial differs from the recently reported COIN trial[10~~15~~] in that we randomized all eligible ELBW infants irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven limited ventilator strategy with infants who were to receive surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of comparing current NRN practice in a number of centers with previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold approach for intubation and the initiation of mechanical ventilation.[6,7] We believed that testing this complete approach would provide a more relevant result as units currently using early CPAP tend to have a higher threshold for intubation.

Formatted: Font: 12 pt, Superscript

We prospectively identified safety outcomes that we chose to follow as investigators. These included; the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H2O compared to the use of early surfactant.

The SUPPORT Trial was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we prospectively agreed to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our study has demonstrated that intent-to-treat with early CPAP and a strategy of limited ventilation compared to surfactant given within 1 hour of birth was associated with a non-significant decrease in death by 36 weeks PMA or BPD as defined by the need for oxygen at 36 weeks from 54.1% to 48.7%. We also noted a significant 8.2% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.2 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that the lower incidence of death in this strata along with significantly decreased durations of mechanical ventilation, a decreased need for intubation and exposure to post natal steroids and a reduction in BPD in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Conclusions:

Compared with infants randomized to be intubated in the delivery room and receive surfactant within 1 hour of birth, infants between 24 and 27 6/7ths weeks gestation assigned to treatment with CPAP and a strategy of limited ventilation have a non significant reduction in the incidence of death or BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse neonatal outcome. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

It may be good to emphasize two interventions rather than two outcomes as some may think we separated the outcomes into two papers.

Wally

I think the two titles could be;

SUPPORT Trial: ventilatory management outcomes

SUPPORT Trial: saturation target outcomes

Or something to that effect

Rose

Dear Rose
Wade and I will develop a final CPAP-Surf paper and Wally will develop the oximeter paper
_ I don't follow David's suggestion and I think we should proceed as planned
The only modification we could consider is to list the subcommittee and the indicate the PI. I am OK with what we are doing.
Our final paper will incorporate all suggestions to date where feasible nd be of appropriate length – 2700 words and abstract 250 words etc.
We will get this to you within the next 5 days. Wally can you do the same for your paper??
Rose I would like to indicate to the NRN that we have received all the input we need and we will now modify and submit.
Otherwise this process will take forever. We should let the journal have their input
The only question is whether we think that the results are important enough for an expedited process??
I would probably say no and go ahead and submit the 2 together

Neil

Subject: Re: ****CONFIDENTIAL SUPPORT DRAFT MANUSCRIPTS*******

Rose,

I reviewed the companion papers and have some general comments about each as well as some minor editorial suggestions.

Finer's Paper

Although I believe there is some logic to reporting the two parts of this trial separately but as companion papers, there is the risk that one can be reported without the other, at least initially (unless there is some agreement in advance). I hope this will be unlikely as the two are inextricably intertwined in the actual trial as it was conceived. For this reason, I believe that each should bear the title of Neil's first author primary paper, which then deserves a subtitle indicating what part of the trial is being presented and discussed. With respect to the paper for which Wally is the first author, it needs the general title from Finer's paper and it should retain the subtitle as proposed by Wally.

In the abstract in the Results section, without going to the tables, the last two sentences are confusing with respect to their linkage. That is, the first statement is focused clearly on the 24-25 weeks stratum. The latter applies to the whole group, including the larger infants. Thus, the second statement should make this clear otherwise the reader will link the two statements. Likewise in the Conclusion section of the abstract, there is reference to "such" infants. The naïve reader will not know based upon the proceeding section to what "such" infants refers.

In the Introduction section of the manuscript, there is a statement that "overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI)." Presumably this is related to reference 14, but the proceeding review does not seem to justify the part of the sentence that says "may do so for the most immature infants," although such a statement is a desirable preamble to the present study. What is the evidence for this statement?

At the end of the Introduction, the last sentence seems like an "add on," although it is essential to the design of the trial. I realize that is the topic of the second paper, but more may need to be said about the actual design of the study and its incorporation of an oximetry randomization.

In the Methods section, the reference "purpose-altered" oximeters is not informative. A naïve reader would not know what is meant and the oximetry part of the trial would not be discussed in this paper as proposed.

In the section on the CPAP Arm, there is a statement "CPAP infants were not to be intubated for surfactant only in the DRŠ." Although it becomes clear later in the paper, it is not clear at this point what this means - whether the infants are not to be intubated just because someone wants to give them surfactant or that they were not to be intubated for surfactant only in the DR, but could be intubated later for this purpose. This should be clarified at this point in the paper.

In the NICU management section, "clinically significant patent ductus arteriosus" will need to be defined. In the Results section, the statement about the primary outcome and the other important findings with respect to the 24-25 stratum should be moved to the beginning of this section followed by the other statistics. This might require reordering of the tables but they are out of order at this point anyway with reference to Table 4 occurring before

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Table 3. Also in this section, I think that the reference to "non-significant" reductions is not useful. Either a finding is statistically significant or it is not based upon the criteria set in advance. The results can simply be stated if a trend needs to be pointed out to the reader. This is done several times in this section. This kind of phraseology is also used in the Discussion and should be avoided.

In the Discussion, one of the paragraphs ends with the statement that "we believe that this lower incidence of death in these infants along with reductions in BPD, ROP, significantly decreased durations of ventilation and oxygenationŠ represents a substantial clinical benefit compared with the initial use of early surfactant." Most of this opinion seems unsubstantiated by the actual data in this study. Perhaps a more measured interpretation would be reasonable.

Although there is a statement that the study was not powered to detect interaction between the two interventions (one of which was not discussed in this paper) and the evaluation of such interactions was done and none were found. This is an unusual statement and it is at least paradoxical. Unfortunately, it is probably unavoidable.

In the Conclusions section, the statement should focus on the primary outcome which is negative and the secondary outcome which is perhaps the most important finding related to the 24-25 week stratum. The last paragraph of the paper should be rewritten to reflect the major findings.

Wally's Paper

Wally's paper needs to have the same title as Neil's paper using the currently proposed title as the subtitle.

In the second paragraph of the Introduction, in reference to the survey, the statistics are confusing because the comparisons in the parentheses are not explicit. Unless one went to reference 5, the statement would not be clear. In the Methods Section, in the paragraph on "Assessments," would the reference to the primary outcome as death before discharge and/or threshold retinopathy of prematurity be sufficiently characterized with only an "and" or "or?" Is it one or the other or really both? In one place, in the "Statistical analysis" section and in several places in the Results, there are missing numbers which I assume will be supplied.

Once again in the Discussion, I would recommend starting the section with the major finding first and then moving into the history. This discussion is reminiscent of the one for the phototherapy manuscript, where secondary tradeoffs are interacting in important ways, "teeing up" difficult decisions.

This manuscript is a little more clear than Neil's (probably because I read it second) in its current form and requires only minor edits. A major issue is the fact that interactions between these two interventions (ventilatory and oxygenation) cannot be fully elucidated. This will be frustrating to some readers, but it is unavoidable. Another unavoidable circumstance is the tremendous overlap of the targets which will frustrate or limit further interpretation of the results.

Congratulations to Neil and others for conducting a very difficult trial which is important and provocative.

Sincerely yours,
David

Thanks!!!
Rose

Hi Ed, Av, Jon and David,

You were included on the previous email and I am writing to ask a big favor.

We would like you to consider doing an internal review for these papers and providing me with written comments by 3 PM on 11/16. Let me know if your schedule permits. If you are not able to meet the time frame planned, let me know. There is urgency to submission of the papers.

Thanks in advance!!!
Rose

Subject: ****CONFIDENTIAL SUPPORT DRAFT MANUSCRIPTS*******

Hi,

Attached are the two papers in draft form for the SUPPORT Primary outcomes. As noted, there is an increase in death in the lower saturation group (20%) versus the higher saturation group (16%).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

This information is confidential and a plan is in place for DSMC communication with ongoing trials of oxygen saturation. If you are contacted by any investigators from other trials or elsewhere, do not share this information. If necessary, refer them to me.

The plan for submission is as follows:

November 16 - 4 PM - call for Steering committee and authors to discuss papers. In the meantime, feel free to send comments to Neil and Wally. The call in number is:
866-675-3256 with passcode 560152#

If you are not going to be on the call, send comments in advance or designate someone to serve in your absence.

Immediately following the call, the manuscripts will be finalized for NICHD clearance and for submission to the New England Journal of Medicine.

Thanks in advance to everyone for all their hard work!!!
Rose

Hi Rose,
Personally, I would like to advocate that Ed Donovan and Vivek Narendran both be listed as Cincinnati authors on the CPAP Surfactant manuscript since Ed and Vivek did a lot to move forward the study up front and Vivek was instrumental during the trial. (Ed did a lot with initial start up and education, hosting the training, producing the training video, and was the Cincinnati PI at the beginning of the study). I would like to be listed as the author from Cincinnati on the Oxygen Saturation.
Thanks,
Kurt

Subject: Saturation paper

Hi Wally,

Just wondering,

Did you intend to have me listed as a co-author on the saturation paper? I received your note sent to 'all authors'.

At present, I am listed only as the Center PI at Rochester in the Biolerplate.

Rochester's protocol PI for SUPPORT was Nirupama Laroia, so she is appropriately listed as the author from Rochester.

However, I have carried a significant responsibility for the ROP data form, training, instructions, monitoring, etc. for the ROP primary outcome -- I think we could justify adding me to the authors list.

Subject: Re: ****CONFIDENTIAL SUPPORT DRAFT MANUSCRIPTS*******

Rose,

I reviewed the companion papers and have some general comments about each as well as some minor editorial suggestions.

Finer's Paper

Although I believe there is some logic to reporting the two parts of this trial separately but as companion papers, there is the risk that one can be reported without the other, at least initially (unless there is some agreement in advance). I hope this will be unlikely as the two are inextricably intertwined in the actual trial as it was conceived. For this reason, I believe that each should bear the title of Neil's first author primary paper, which then deserves a subtitle indicating what part of the trial is being presented and discussed. With respect to the paper for which Wally is the first author, it needs the general title from Finer's paper and it should retain the subtitle as proposed by Wally.

In the abstract in the Results section, without going to the tables, the last two sentences are confusing with respect to their linkage. That is, the first statement is focused clearly on the 24-25 weeks stratum. The latter applies to the whole group, including the larger infants. Thus, the second statement should make this clear otherwise the reader will link the two statements. Likewise in the Conclusion section of the abstract, there is reference to "such"

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

infants. The naïve reader will not know based upon the proceeding section to what "such" infants refers.

In the Introduction section of the manuscript, there is a statement that "overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI)." Presumably this is related to reference 14, but the proceeding review does not seem to justify the part of the sentence that says "may do so for the most immature infants," although such a statement is a desirable preamble to the present study. What is the evidence for this statement?

At the end of the Introduction, the last sentence seems like an "add on," although it is essential to the design of the trial. I realize that is the topic of the second paper, but more may need to be said about the actual design of the study and its incorporation of an oximetry randomization.

In the Methods section, the reference "purpose-altered" oximeters is not informative. A naïve reader would not know what is meant and the oximetry part of the trial would not be discussed in this paper as proposed.

In the section on the CPAP Arm, there is a statement "CPAP infants were not to be intubated for surfactant only in the DRŠ." Although it becomes clear later in the paper, it is not clear at this point what this means - whether the infants are not to be intubated just because someone wants to give them surfactant or that they were not to be intubated for surfactant only in the DR, but could be intubated later for this purpose. This should be clarified at this point in the paper.

In the NICU management section, "clinically significant patent ductus arteriosus" will need to be defined. In the Results section, the statement about the primary outcome and the other important findings with respect to the 24-25 stratum should be moved to the beginning of this section followed by the other statistics. This might require reordering of the tables but they are out of order at this point anyway with reference to Table 4 occurring before Table 3. Also in this section, I think that the reference to "non-significant" reductions is not useful. Either a finding is statistically significant or it is not based upon the criteria set in advance. The results can simply be stated if a trend needs to be pointed out to the reader. This is done several times in this section. This kind of phraseology is also used in the Discussion and should be avoided.

In the Discussion, one of the paragraphs ends with the statement that "we believe that this lower incidence of death in these infants along with reductions in BPD, ROP, significantly decreased durations of ventilation and oxygenationŠ represents a substantial clinical benefit compared with the initial use of early surfactant." Most of this opinion seems unsubstantiated by the actual data in this study. Perhaps a more measured interpretation would be reasonable.

Although there is a statement that the study was not powered to detect interaction between the two interventions (one of which was not discussed in this paper) and the evaluation of such interactions was done and none were found. This is an unusual statement and it is at least paradoxical. Unfortunately, it is probably unavoidable.

In the Conclusions section, the statement should focus on the primary outcome which is

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

negative and the secondary outcome which is perhaps the most important finding related to the 24-25 week stratum. The last paragraph of the paper should be rewritten to reflect the major findings.

Wally's Paper

Wally's paper needs to have the same title as Neil's paper using the currently proposed title as the subtitle.

In the second paragraph of the Introduction, in reference to the survey, the statistics are confusing because the comparisons in the parentheses are not explicit. Unless one went to reference 5, the statement would not be clear. In the Methods Section, in the paragraph on "Assessments," would the reference to the primary outcome as death before discharge and/or threshold retinopathy of prematurity be sufficiently characterized with only an "and" or "or?" Is it one or the other or really both? In one place, in the "Statistical analysis" section and in several places in the Results, there are missing numbers which I assume will be supplied.

Once again in the Discussion, I would recommend starting the section with the major finding first and then moving into the history. This discussion is reminiscent of the one for the phototherapy manuscript, where secondary tradeoffs are interacting in important ways, "teeing up" difficult decisions.

This manuscript is a little more clear than Neil's (probably because I read it second) in its current form and requires only minor edits. A major issue is the fact that interactions between these two interventions (ventilatory and oxygenation) cannot be fully elucidated. This will be frustrating to some readers, but it is unavoidable. Another unavoidable circumstance is the tremendous overlap of the targets which will frustrate or limit further interpretation of the results.

Congratulations to Neil and others for conducting a very difficult trial which is important and provocative.

Sincerely yours,
David

Protocol Review
November 2009

SUPPORT - School Age Breathing Outcomes Study: A Proposal for the NICHD Neonatal Research Network
October 21, 2009
Investigators: Timothy P. Stevens, MD, MPH; Richard A. Ehrenkranz, MD; Neil N. Finer, MD

Comments by Kurt Schibler, MD

I am enthusiastic about this study and would like to see it move forward. Here are a few comments for the discussion next week.

1. I would advocate for comparing environmental tobacco exposure in CPAP versus intubation/surfactant arm in addition to the high versus low saturation arm. I do not see this proposed, but the first hit of oxygen may have a quite different than that of an endotracheal tube and microbial colonization.
2. Are cotinine levels being measured at 18-22 months and at 6-7 years for ETS?
3. How are other environmental exposures being evaluated?
4. The comparisons of subgroups with and without BPD should be stratified by gestational age group or correct for gestational age to assure that the groups have similar lung development at the time of the insults.
5. While there is separation in oxygen exposure between high and low O2 saturation groups, there is significant overlap. If there are sufficient patients, might the investigators want a priori to set up a look at highest versus lowest quartile oxygen exposure as well.
6. Perhaps the pulmonologists know how an 8% change in PFT's correlated with respiratory symptoms, need for pulmonary care, or impacts lifestyle (sedentary versus active choices). I think these correlations should be analyzed. In other words what is the clinical and lifestyle significance of this degree of change in PFTs?

---

Hi Neil,
The manuscript looks great! I do have a couple suggested changes and comments (tracking changes/comments on attachment). My most significant comments are:
1. Vivek Narendran should be listed as the Cincinnati author for the CPAP paper. I have advocated that Ed Donovan also be an author as he did a great deal of work leading up to this trial, hosted the education session, produced the video and was the PI here for the first two years of the trial. Of course this decision is up to the steering committee.
2. The definition of BPD should be consistent between the CPAP and Oximetry manuscripts and should be clear in the Methods. I would favor the physiologic definition. Oxygen at 36 weeks should also be reported as you have for comparisons with other trials.
3. I think the term non-significant reduction is overused and should be reserved for use only if results are very close to significance.
4. In the discussion in the 24-25 week strata, BPD and ROP are reported as reduced. BPD is not significantly reduced and ROP is not reported in that strata.

Ed Donovan will be on the call Monday. I will not as I will be out of the country and with limited to no internet access.

Thanks for your passion, hard work, and inspiration!!
Kurt

Acknowledgements (I sent several questions regarding the boilerplate to Stephanie for clarification with Wally's paper)

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Running head: Early CPAP versus Surfactant and outcomes of prematurity

Key words: CPAP, bronchopulmonary dysplasia, extremely low birth weight infant, neonatal mortality, surfactant

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilator strategy. Infants randomized to surfactant were intubated and received surfactant within 60 min minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while in the NICU and receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, **defined as the need for supplemental oxygen at 36 weeks was 49% in the CPAP group versus 54% in the surfactant group, (RR 0.91, 95% CI 0.82, 1.00, p=0.06 when adjusted for gestational age, center and familial clustering),** There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.019) and fewer required intubation or post natal steroids for BPD, (p<.001).

Formatted: Highlight

Comment [cc2]: The definition of BPD should be the consistent in both arms of the SUPPORT Trial. In the Oximentry paper it is reported as the physiological definition of BPD

Formatted: Highlight

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Conclusions: The use of CPAP in ~~such~~ infants 24 to 28 weeks gestation is an effective evidence based alternative to intubation and surfactant.

Comment [cc3]: Or extremely premature

Introduction:

At the present time, there is no agreement as to the optimal approach to respiratory support for the extremely low birth weight (ELBW) infant following delivery. Positive End Expiratory Pressure (PEEP) has been shown to be of benefit in maintaining functional residual capacity (FRC), and continuous positive airway pressure appears beneficial during cardiopulmonary resuscitation[1]. Gregory et al in 1971 first demonstrated that the use of CPAP started at approximately 5.9 hours (+12.4hrs) for their infants < 1500 gm at birth, improved oxygenation[2] in newborn infants with respiratory distress; these observations were followed by prospective studies that demonstrated improved survival in premature infants treated with early CPAP[3]. A review of prospective studies evaluating early (not delivery room) CPAP in the pre-surfactant, pre-antenatal steroid era found that early CPAP improved survival overall and for infants greater than 1500 gm, and was associated with increased pneumothoraces.[4] A more recent review of prophylactic CPAP started in the delivery room reviewed only 2 available trials and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

found no significant difference between the CPAP and conventionally managed infants and noted a trend to increased adverse outcomes for the CPAP treated infants.[5]

There is substantial retrospective evidence suggesting a benefit for early CPAP in experiences from both the US and other countries.[678] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following the initiation of early CPAP treatment.[91011]

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[1213] The surfactant trials preceeded widespread use of antenatal corticosteroids to promote lung maturation. Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI). [14]

The recent COIN trial randomized 610 infants from 25 weeks 0 days to 28 weeks 6 days gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[15] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analyses[44], and a reduction in death or the need for oxygen at 28

Formatted: Font: 12 pt, Superscript

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with no difference in death or BPD at 36 weeks.

In view of the current interest in the use of early CPAP and the lack of prospective comparisons of this approach with the evidence based intervention of prophylactic or early surfactant, the SUPPORT study was designed to compare these approaches for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design, and the results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324).This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters. These results will be separately reported.

The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a protocol driven limited

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

ventilator strategy in infants of 24 to 28 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Comment [cc4]: Neil, I think BPD should be defined here and should be consistent between manuscripts. I favor the physiological definition.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born at a randomizing center without known malformations, for whom a decision had been made to provide full resuscitation, and parental consent had been obtained. The infants were randomized within each center to 2 gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used at all sites for the delivery room administration of CPAP. CPAP or ventilation with PEEP both at a recommended 5 cm H_2O was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU using the T-piece resuscitator or equivalent device and a face mask or nasal prongs. CPAP infants were not to be intubated for surfactant only in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications **(need ref)** including failure to respond to positive pressure ventilation (PPV) with evidence of continuing cyanosis or bradycardia, the need for chest compressions, the need to administer intratracheal medications, or other situations in which the resuscitation team determined that surfactant is urgently required.

Formatted: Highlight

NICU management: Intubation was allowed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery. While

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

intubation was never required by protocol, CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within one hour of intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean airway pressure (MAP) < 10 cm H2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations CPAP infants were treated using NICU standardpractice.

Surfactant Arm: All infants were to be intubated within 1 hour of life and receive surfactant, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30 An FiO2 ≤ 35 with a SpO2 $\geq$88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate $\leq$ 15 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and be hemodynamically stable with no evidence of clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms of the trial intubation could be performed at any

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, and thus multiples, were randomized to the same arm of the trial.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, (using the NRN occurrence of death or survival with BPD of 67% using the year 2000 data), -and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months (using the NRN occurrence of NDI of 61% -using year 2000 data) by 10%. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1312 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the 2 factorial arms.

Comment [cc5]: This is a long sentence. It might be broken into hypothsis and then a second sentence giving the baselines.

In addition there was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which required an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks and assigned a diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support. [16,17]

Comment [cc6]: This is confusing because BPD is not defined in the methods, only in the abstract. Again it should be defined with primary outcome and this can be included there. It should be consistently reported in the two manuscripts.

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

known. The primary analyses focused on the percent of each Group who developed their respective outcome measure of survival without BPD at 36 weeks. Adjustment was performed as pre-specified for gestational age stratum, center and familial clustering using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. A two-sided P value of less than 0.05 was considered statistically significant. An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. (Lan-DeMets spending functions with Pocock (O'Brien-Fleming) boundaries were used to develop stopping rules for interim safety and efficacy monitoring. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and a combination of any of the above events.

The study was approved by Human Subjects Committees at all participating sites and RTI, the NRN data center that managed and analyzed all the data, and parental consent for participation in the trial was required before delivery

Results:

There were 1316 infants enrolled in this trial from Feb 2005 through to Mar 1 2009-. The trial was temporarily suspended by the DSMB because of concerns regarding the oximetry data in November 2005 but after a complete review the trial was continued in February 2006 with no protocol changes. The patient descriptive information for the CPAP versus Surfactant arms is shown in Table 1. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, Apgar scores or

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

race between the 2 treatment groups. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant.

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants, and surfactant was given to 14% of the CPAP versus 51% of the surfactant group; 67% of the CPAP infants received surfactant in the delivery room or NICU, compared to 99% of those in the surfactant group (all p<0.001). Intubation in the DR occurred in 34% of CPAP infants compared with 93% of surfactant infants, p<0.001, Table 2.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post conceptional age was non-significantly reduced for the CPAP group compared with the Surfactant group, 49% versus 54%, (RR 0.91, 05% CI 0.82, 1.00, p=0.060) when adjusted for gestational age, center and familial clustering as prespecified. Death during the hospitalization was 4% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata,, 24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03, Table 4. There was a non-significant reduction in the occurrence of BPD using the need for supplemental oxygen, 40% vs 44%, RR 0.93, 95% CI 0.82, 1.06. Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39% vs 41%, RR 0.99, 95% CI 0.87, 1.14), and a non-significant reduction in the occurrence of death or Physiologic BPD at 36 weeks in the CPAP group, (48% vs 51%, RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room nor any differences in length of stay, or days of oxygen for survivors, or discharge on oxygen. (Table 3). More CPAP

Formatted: Highlight

Comment [cc7]: Define BPD in methods

Formatted: Highlight

Comment [cc8]: I think non-significant reduction is overused, a RR of 0.99 with these confidence intervals is not different.

Formatted: Highlight

infants were alive and off mechanical ventilation by day 7, (p=0.019). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All infants in the Surfactant arm were intubated, compared with 83% of the CPAP infants who required intubation during their nursery course, (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants, 7% vs 13%, p=.0005). The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18] was non- significantly reduced in in the CPAP compared to the surfactant infants, (23% vs 31%, RR=0.75(0,54, 1.05)

Strata Results: 24 – 25 weeks Gestation

There were more non-Hispanic black infants in the CPAP group compared with the Surfactant group. **The differences are shown in Table 4 (24-25 wk Strata).** CPAP infants had a significantly lower mortality while hospitalized 24% vs 32%, RR=0.74, 95% CI 0.57, 0.98, p=0.03. There was a significantly higher exposure to postnatal steroids for BPD, 20% vs 13%, p=0.02 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata.

Comment [cc9]: These racial and ethnic differences are not shown in table 4.

Formatted: Highlight

26-27 weeks Gestation

There was no difference in mortality for the CPAP vs Surfactant groups, 10% vs 11%. The CPAP infants required fewer days of oxygen, 40.6 vs 47.1, p=0.01, and lesser days of mechanical

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

ventilation, 11.3 vs 14.9, p=0.01, and fewer infants received postnatal steroids for BPD, 3% vs 8%, p<0.01.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare early CPAP with early surfactant given within an hour of life in ELBW infants and the only prospective randomized trial comparing CPAP to any other ~~outcome~~intervention -that enrolled infants of 24 weeks gestation. In a preliminary study we found that 100% of infants of 23 weeks gestation required intubation in the DR, and thus decided that such infants would be unlikely to be successfully treated with CPAP alone following delivery.[19] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[20]

Our study differs from the recently reported COIN trial[~~15~~15] in that we randomized all eligible ELBW infants of consenting families irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven limited ventilator strategy with infants who all received surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold approach for intubation and the initiation of mechanical ventilation, and the current practice of a number of NRN units.[6,7] We believed that testing this complete approach would provide a more relevant result as most units currently using early CPAP also tend to have a higher threshold for intubation.

Formatted: Font: 12 pt, Superscript

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our study has demonstrated that early CPAP and protocol driven limited ventilator strategy when compared with surfactant given within 1 hour of birth was associated with a non-significant decrease in death or survival with BPD as defined by the need for oxygen at 36 weeks from 54% to 49%. We also noted a very significant 8% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.5 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that this lower incidence of death in these infants along with- reductions in **BPD, ROP**, significantly decreased durations of ventilation and oxygen, a decreased need for intubation and exposure to post natal steroids in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

Comment [cc10]: This is not shown in the table. BPD is not significantly reduced and ROP is not discussed in this strata.

Formatted: Highlight

We prospectively identified a number of safety outcomes that we chose to follow as investigators. These included the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks, initially defined as pneumothoraces but later altered to include pulmonary interstitial emphysema, pneumomediastinum and pneumopericardium. We did not find an increase in airleaks with the use of early CPAP at 5 cm H2O compared to the use of early surfactant.

The SUPPORT study was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we did prospectively agree to

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Conclusions:

Compared with the use of surfactant within 1 hour of birth, ELBW infants between 24 and 27 6/7ths weeks gestation at birth treated with CPAP and a protocol driven limited ventilator strategy have a non significant decreased incidence of death or survival with BPD based on the need for oxygen at 36 weeks PCA with no demonstrable increase in any adverse neonatal outcomes. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

Hi Wally!

I had the opportunity to read the most recent version of the manuscript that you forwarded. I remain impressed by your ability to rapidly generate a concise manuscript about a complex study. I do have a few thoughts/suggestions:

1) On page 1 of the title page, my name should have the superscript 6 next to it (Utah), rather than 5 (Women and Infants Hospital/Brown).
2) In Methods, you note appropriately that the study was not powered to assess interaction of the two arms in the SUPPORT study (sat target vs CPAP/surfactant). In Neil's manuscript, however, he reported in the last paragraph of the Discussion that 'While the study was not powered to detect an interaction between the two interventions, we did propsectively agree to evaluate such interactions and none were found'. A similar statement in your manuscript may be useful as well as make the two manuscripts consistent.
3) It is unfortunate that the causes of death are unavailable to assess the biologic plausibility of hypoxia as a contributing factor re: the significant difference between the high and low targeted SpO2 groups.
4) Abstract, background, line 1: Should it be 'the incidence of threshold prematurity'?
5) Abstract, background, line 2: 'Oxygenation levels lower than previously maintained' may be less clear to the reader than 'oxygenation targets lower than previously employed' (or something similar).
6) Abstract/methods: Would it be clearer to make the second half of the composite outcome 'death before NICU discharge'?
7) Page 10, paragraph 1, line 9: Change 'levels' to 'PaO2'?
8) Page 10, paragraph 2, line 4: Do we need to describe the study population in the survey study by BW or GA, or was it truly all infants cared for in thoe study NICUs?
9) Page 13, line 1: Should we add that randomization occurred at birth and that randomization was implemented in the DR?
10) Page 15, line 4: Per the protocol on the NRN website, it appears that chest compressions and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

epinephrine in the DR were also trcaked as saftey indicators.
11) Page 15, Results paragraph 1: May it be useful to provide a bit more detail about the temporary hold on the study, i.e., the fact that infants not requiring supplemental O2 frequnetly had SpO2s higher than assigned.
12) I agree with Ed Bell's suggestion that it may be useful for the reader to know that the data indicate 1 more death before discharge for every 2.6 less cases of threshold ROP in the low target group.
13) It is probably worth adding to the discussion that the real importance of the difference in threshold ROP re: blindness, other permanent visual disability will be evident only after these functional outcomes are assessed at 18-22 months follow-up.
14) Table 3: The data for the two groups and the P value for the row 'Alive off mechanical ventilation by day 7) are missing.

I hope these are useful. If other thoughts occur before the teleconference on Monday, I will certainly forward them.

Roger

See below for some answers (in green). Others I'm still working on. New tables 1, 2, and 3 are attached, as are tables for cause of death (Table 1 and COD table have unadjusted p-values, all other p-values for outcomes are adjusted). Note that the DSMC was concerned about the "other" COD category. These are mostly cases where a terminal event rather than an underlying cause of death was recorded on the GDB forms. We may have to query the centers to obtain more information. See the end of the COD document attached for "other" causes that have been moved into other categories, as well as those that are still in the "other" category of the table. Please let me know if any adjustments to these categories need to be made. I have not updated any numbers in the text of Wally's paper yet, but I'll work on that and the other outstanding issues this weekend.

Subject: Re: Manuscript

Wally

Thanks for quickly turning this around.

We refer ro nonrandomized studies in several sections of the paper. Is observational a better word?

Sometimes "observational" may be ok but most studies were pre post studies (following a change in oxygen saturation targeting). These studies could be called "controlled" which is a better level of evidence than observational. I have been more specific in how I refer to those studies in the revised draft.

There is no citation of the STOP-ROP paper in the manuscript. Although this looked at saturation levels in pretheshold ROP, it should probably be listed.

It was quoted (ref 20) but the incorrect reference was put inadvertently in the reference list. This is now corrected. If we are below the NEJM word limit, I can add more details (especially that the intervention was late in the hospital course).

Methods - end of the first paragraph - delete "before delivery" as part of the consent process. Although this occrred in the vast majority, there were a few that occurred after delivery for a variety of reasons.

This happened because the protocol allowed it. I was trying to keep it short so may omit the details (exception).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Wold it be possible to include the scatter graph of actual versus monitor oximetry levels included in the stdy protocl in the supplementary/appendix materials? We explain this 3 percent offset in the methods on page 12, bt the graph really shows it to those who are visually oriented.

Abhik: What do you think?

At the bottom of page 12 we stated that sat targets were maintained by "clinicians.". It may be more accurate to say adjustments.... were performed by "NICU or clinical staff.". This way, everyone (nrse, md, resp therapist) are included and it is acucrate reporting.

Agree, change made.

In the methods section (page 13) nder assessments - should we (or do we even have space) report abot the 14 day safety monitoring??

Rose: What should I say about the 14 day safety monitoring?

Leave 18-22 month FU out of the methods section on page 13 I this shold be incluuded in the discussion.

Moved to the Discussion section as suggested.

Bottom of page 14 I should we add one sentence about the first dsmc look at the data that occurred due to concern with compliance with sat levels are the part of the investigators as this happened prior to 25 percent enrollment? I suggest "dsmc evaluated sat data upon reqest of investigators to evaluate compliance after enrollment of XX infants.". You do explain this in the results and it leaves the reader wondering why we did this.

Done

Results - first line page 15 I enrollment started in Feb 2005 not Jan 2004 (I think).

Marie: Can you check?

MG: First enrolled infant was in Feb 2005

Discussion - second line - you stated "standard" practice. I recommend

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

changing this to "common" practice as there was no AAP guideline or otherwise indicating "standard."

Done

Page 17 - end paragraph- reviewers may want to know abot the lower sat infants and deaths (ron goldberg's comment at the sc meeting.

I think this will need further explanatory analysis. We may be able to address with Kaplan Meier plot and cause of deaths (which I have requested to Marie).

The last paragraph of the discussion should restate the primary outcome and the two significant otcones of ROP and BPD benefit.

Done, except BPD was only decreased when analyzed by O2 weaning, not by physiologic definition and the competing outcome of death eliminated the BPD benefit. Thus, I have not emphasized a BPD benefit.

Table 1 has 655 in low sat group and 661 in high sat group. On table 2 many of the denominators are 654 in low sat group and there is a denominator of 662 on several of the high sat outcomes - we need to fix this.

Marie: Can you correct these? Can you also verify the figure numbers?

Also, threshold rop/death says 17/605 for low sat group (should be 170/) and high sat group says 198.616.

Corrected

Figure 1 - is there a way to have "pregnancies" assessed for eligibility?". That is actually how this nfolded.

Marie: Please check.

MG: We could convert certain numbers to pregnancies, but one of the problems is that those numbers are terrible to begin with. They do not account for pregnancies that were screened but did not result in deliveries that made it into the GDB or SUPPORT. If we want to give readers an accurate picture of how many women were screened/eligible we would be better off citing numbers from the Antenatal Consent study.

For figure 2 - is there any way to "statistically" assess if we reached an adequate separation between the two groups??
Marie: Can you analyze? I am sure they are statistically significant.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

MG: A Rank Sums test of the difference of the medians of the two distributions in Figure 2 has a p-value of <0.0001.

Also -
I also pulled the May 2009 NeoProm confidential update.
As of that meeting, the following nmbers were recruited into the trials:

BOOST II australia 658/1200
BOOST II New zealand -291/320
BOOST UK -332/1200
COT -684/1200

Each trial has a dsmc and likely monitoring AE's like mortality. I have spoken to NICHD and NHLBI leadership. The other trials are enrolling children following delivery. Our dsmc meets Nov 4 -the leadership would like input from or DSMC prior to any possible confidential dscussions with other dsmc's. Also the observed mortality between the two sat groups (16 and 20 percent) is tighter than the nrn range of mortality from historical data provided to our dsmc (9.5-32 percent deaths by day 14).

Dear Rose, Neil, Marie and Abhik:

Enclosed is the next draft. I have received comments from some of you and from Michele, and I have responded to the issues raised.

I talked with Abhik and he agreed Marie should get a Kaplan Meier plot for mortality (New Fig 2).

I think it is ready to be sent to the rest of the Subcommittee.

Title: Randomized Trial of Oxygen Saturation Targets in Premature Infants-the SUPPORT Trial

W A Carlo, MD[1], N N Finer, MD[2] and on behalf of the SUPPORT Subcommittee for the NICHD Neonatal Research Network. [1]University of Alabama at Birmingham, Birmingham, Alabama, United States and [2]University of California San Diego, San Diego, California, United States.

Background: Recent non-randomized studies suggest that the incidence of retinopathy of prematurity (ROP) decreases in premature infants with oxygenation levels lower than previously maintained. However, it is important to determine if lower oxygen saturation targets reduce ROP without increasing adverse outcomes

Objective: To test the hypothesis that a lower oxygen saturation target decreases severe ROP and/or death in extremely premature infants.

Design/Methods: 1316 infants of 24 0/7 to 27 6/7 weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95% using masked oximeters or part of a 2x2 factorial trial. The primary outcome was a composite of severe ROP (Type 1 threshold ROP/surgery/bevacizumab) and/or death.

Results: Severe ROP/death did not differ between the oxygen saturation target groups (Table; adjusted for stratification factors: study center, gestational age group, and familial clustering). Severe ROP was decreased (P<0.001) in the lower oxygen saturation target group but death was more frequent (P=0.045, Table). Oxygen use at 36 weeks significantly decreased in the lower oxygen saturation target group but oxygen use by the physiologic definition or oxygen use at 36 weeks/death did not decrease. Other outcomes did not differ between the groups (Table).

Conclusions: Lower oxygen saturation (85-89%) targets did not significantly decrease the combined outcomes of severe ROP/death but resulted in an increase in mortality that partially offset a decrease in severe ROP. The increased mortality is of concern as lower saturation targeting is increasingly being advocated because it has short term ROP benefits.

	Lower O2 Saturation Group n/N (%)	Higher O2 Saturation Group n/N (%)	Adjusted Relative Risk1 (95% CI)
Severe ROP/death	170/605 (28.3)	198/616 (32.1)	0.90 (0.76, 1.06)
Severe ROP	43/483 (8.9)	95/514 (18.5)	0.51 (0.37, 0.71)
Death before discharge	130/654 (19.9)	107/662 (16.2)	1.27 (1.01, 1.60)
Bronchopulmonary dysplasia (physiologic) at 36 weeks	205/540 (38.0)	237/568 (41.7)	0.92 (0.81, 1.05)
Intraventricular hemorrhage, grade 3 or 4	83/630 (13.2)	81/640 (12.7)	1.06 (0.80, 1.40)
Necrotizing enterocolitis, stage ≥ 2	76/641 (11.9)	70/649 (10.8)	1.11 (0.82, 1.51)

Hi Rose,
Personally, I would like to advocate that Ed Donovan and Vivek Narendran both be listed as Cincinnati authors on the CPAP Surfactant manuscript since Ed and Vivek did a lot to move forward the study up front and Vivek was instrumental during the trial. (Ed did a lot with initial start up and education, hosting the training, producing the training video, and was the Cincinnati PI at the beginning of the study). I would like to be listed as the author from Cincinnati on the Oxygen Saturation.
Thanks,
Kurt

Hi Wally,

Just wondering,

Did you intend to have me listed as a co-author on the saturation paper? I received your note sent to 'all authors'.

At present, I am listed only as the Center PI at Rochester in the Biolerplate.

Rochester's protocol PI for SUPPORT was Nirupama Laroia, so she is appropriately listed as the author from Rochester.

However, I have carried a significant responsibility for the ROP data form, training, instructions, monitoring, etc. for the ROP primary outcome -- I think we could justify adding me to the authors list.

Dear SUPPORT Subcommittee members:

Enclosed is a draft of the oxygen saturation paper for your comments. I need everyone's comments before we can submit to the Publications Subcommittee and the whole Steering Committee which gets it at the same time. I am also enclosing the first draft of the PAS abstract which is currently slightly above the word limit.

Wally

We should be consistent and present only the adjusted results for the survival analysis.

Thanks

Abhik

Subject: RE: Oxygen Saturation paper for your comments.

Attached is the Oxygen Saturation paper with my edits and comments. I have updated all numbers and p-values. I have added to the methods section on statistical analysis, and I have added the survival analysis. Instead of using Kaplan-Meier analysis I have used Cox regression in order to adjust for stratification and clustering as in the other analyses. The results were similar, although the difference in the survival curves was significant (p=0.045) after adjustment and non-signficant in the KM analysis without the adjustments. See attached for the two survival curves for comparison.

I will also update all numbers in the CPAP paper and send that out as well.

Marie

I think neil and wally on behalf of the support subcommittee of the nichd nrn is fine. If space permits, marie and wade can be added. Limitation in author number was instituted because the authors were taking up to 25 percent of alloted space.
I need the abstract in the next day or so for nichd clearance.
Thanks

Hi Wally
I am working on the abstract for CPAP and Surf On both Abstracts I would like at least you and me as authors and then whatever follows I will put Finer, Carlo, you can do the flip side I don't know how many authors the NRN requires on abstracts but we will have 2 anyway- if we can do more I would put Wade, Rose and Marie.
Let me know
Neil

Neil:

I agree with Abhik that we should soften the results that are related to the exploratory subgroup analyses. In many ways, our work sets standards for our field and is held to the highest scrutiny.

Neil:

Some suggested editorial changes are attached, that cuts down on the words a little bit. I have expressed my reservations about the boldness of the conclusion before; so I won't repeat that again! I can live with it if it is acceptable to the subcommittee and the steering committee.

Thanks

Abhik

Hi Wally,
Here are my tracked changes edits, questions, suggestions on the Saturation paper.

I'm generally feeling like we have not done enough examination of the data to feel comfortable with the conclusions (although I don't really think they will change.) I realize you are busy working on that remedy.

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study: **[Because you say 'in addition to those listed as authors' , you need to remove those already listed as authors from the Boiler Plate below. dlp]**
