ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95%. The primary outcome was a composite of threshold retinopathy of prematurity and/or death.

Results

Threshold retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; [redacted] Death was more frequent in the lower oxygen saturation target group (20 vs 16%; RR 1.27; CI 1.01, 1.60; [redacted] while threshold retinopathy occurred less often in these infants (9 vs 18%; RR 0.51; CI 0.37, 0.71; [redacted] **[We may wish to put the NNT comments in here.--dlp]**

Conclusions

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcome of threshold retinopathy/death but resulted in an increase in mortality that partially offset a decrease in threshold retinopathy. The increased mortality is of concern as lower saturation targeting is increasingly

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity was reduced when conventional~~increased with~~ exposure to prolonged ~~unrestricted~~ oxygen in premature infants was restricted in randomized controlled trials performed in the 1950s.[1] **[This is a little iffy, referencing a review instead of the original papers, but it may be ok this far out. It is not appropriate to call the 1956 Kinsey trial "unrestricted oxygen" because they gave FiO2 0.50 carefully for 4 weeks (conventional treatment). ~~We need to address it otherwise.~~ --dlp]** However, in subsequent years, the practice of restricting oxygen supplementation was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6, 7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy[12], and other morbidities. Although a multicenter prospective observational study [13] could not determine an association between oxygen levels and retinopathy, a single center randomzied trial~~cohort study~~ using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels ≥ 80 mmHg in a secondary analysis.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations of lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3,4,5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery was higher in infants cared for in neonatal intensive care units with maximum target oxygen saturation over ≥ 92% as compared to below 92% (3.3 ± 0.3 versus 1.4 ± 0.2%), or greater

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

than ~~≥~~ 98% satiration, compared to less than 98%~~-~~ (5.6 ± 1.1 versus 3.1 ± 0.3%).[5] **]Wally, I could not figure out what the sentence said for sure, but I think this is what you meant. Did I get it right? dlp]** The incidence of severe retinopathy requiring ablation therapy was 27% in units where target saturations were 88 to 98% and only 6% in units where the target was 70 to 90% in a retrospective study comparing outcomes at five neonatal intensive care units.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83 to 95% resulted in a substantial reduction in retinopathy.[4, 15, 16] However, actual oxygen saturations achieved were not reported. Furthermore, mortality and neurodevelopmental outcomes were not reported. While data from these recent prospective observational studies, retrospective studies, or controlled but not randomized studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease the incidence of retinopathy of prematurity, there is no conclusive evidence that these oxygenation levels do so without an increase in serious adverse effects, including the possibility of increased risk of death with lower oxygenation as previously reported.

Formatted: Font: Bold

We conducted a 2 x 2 factorial-design multicenter randomized trial of oxygen saturation targeting and protocol-driven limited ventilator strategy. The oxygen saturation part of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of threshold retinopathy of prematurity or death among infants of 24 to 27 weeks gestational age at birth. The ventilation part of this factorial design trial was used to compare two different respiratory support strategies~~control for the ventilatory approach and test other hypotheses~~ and will be reported separately.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at RTI, the independent data coordinating center, approved the trial. Written informed consent was obtained from the parent or guardian of each participant before delivery.

Patients

Infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation for which a decision had been made to provide full resuscitation were eligible for enrollment at birth. Outborn infants and those with major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of double-sealed opaque envelopes to oxygen saturation targeting of 85 to 89% or 91 to 95% (the lower and higher oxygen saturation target groups, respectively) using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with an output display of 88 to 92% for these oxygen ranges, with an offset of plus 3%, or minus 3% from the display (Massimo Radical Set Pulse Oximeter, Irvine, CA) as previously used to separate oxygen saturations in older premature infants.[17] Thus, for example, an oxygen saturation display of 92% would correspond to an actual oxygen saturation of 89% ~~and~~ or 95% in the 85-89% and 91-95% target groups, respectively. The oxygen saturation values displayed reverted to actual values when less than 85% or higher than 95%, the levels of alarm setting recommended in the protocol. **JI do**

Formatted: Font: Bold

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

not understand what this last phrase about the alarms is saying... did alarms go off at 85% saturation and 95% saturation? or did the protocol recommend that centers set the alarms at these levels?] Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours. Infants weaned to room air but who subsequently received oxygen supplementation before 36 weeks post-menstrual age were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinical, not the research staff. Reports of displayed data by clinical center were provided quarterly for feedback on targeting performance. For the ventilation part of this 2 by 2 factorial design trial, participants were also randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilation strategy.

Assessments

Research nurses recorded all data using standardized definitions included in the trial Manual of Operations. Data were collected until discharge except for retinopathy. ROP examinations were conducted according to published guidelines (AAP/AAO joint statement, ref xx added to references) until the study endpoint or resolution was reached. The unfavorable study endpoint was threshold ROP as described below in at least one eye. Resolution was defined as a fully vascularized retina, or immature vessels or regressing ROP in zone III for two consecutive examinations in each eye. The primary outcome was death before discharge and/or threshold retinopathy. Threshold ROP~~retinopathy of prematurity~~ (New Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative

Group[18]) was coded if any of the following findings were present. ~~up to 55 weeks post-menstrual age:~~

[Note correction of reference # 18. this is the wrong one.~~8. this is the wrong one~~]

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic interventions defined as any of the following for ROP: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, vitrectomy, ~~and~~ or bevacizumab (Avastin).

Other outcomes recorded included only predefined clinical diagnoses and potential adverse events.

Statistical analysis

The primary analysis for the oxygen saturation arm of this factorial trial was a generalized estimating equation (GEE) model that used robust Poisson regression to produce adjusted relative risks comparing incidence rates for infants in each treatment arm who developed the primary outcome. The model produces relative risk estimates adjusted for stratification by center and gestational age as well as for familial clustering due to randomization of multiple births to the same treatment arm. A median actual oxygen saturation value while on oxygen supplementation was determined for each infant to compare the effect of targeting an actual oxygen saturation value between treatment arms.

An absolute difference of 10% between the two treatment groups was considered clinically important. The sample size calculations were based on the rate of death or threshold retinopathy of 50% in the Neonatal Research Network from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or neurodevelopmental impairment at 18-22 months

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

corrected age). Based on an intracluster correlation of 0.12 in this outcome, the sample size was increased by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because this introduced a clustering effect into the design. The required sample size was increased by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the two factorial arms. **[Although it may not have been powered for this, why have we not looked to see if an interaction is apparent? dlp?]**

Formatted: Font: Bold

Intent-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. A two-sided p value of less than 0.05 was considered to be statistically significant. Analyses did not include adjustment for multiple comparisons. An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at ~25%, 50%, and 75% of planned enrollment. In addition, the Data Safety and Monitoring Committee, upon request of the investigators, evaluated the oxygen saturation data after enrollment [redacted] to evaluate compliance with the protocol. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of the above events.

RESULTS

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

1316 infants were enrolled between January 2004 and March 2009 (Figure 1). Survival data was known for all enrollees to discharge, and ROP outcomes among survivors was obtained in 92%. Enrollment was temporarily paused after evaluation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and Human Development Director because of concerns regarding compliance with oxygen saturation targets. Separate analysis of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns, and continued enrollment was approved.

The baseline characteristics of the lower saturation group and the higher saturation group were similar (Table 1). **[I would add to this table the n, percent for each saturation group that went into the CPAP arm. (or if you prefer the prophylactic surfactant arm. This is a baseline characteristic for these infants. --dlp]**

[Dr. Guillet from Rochester notes: I don't know if it is statistically significant, but the low sat group got more surfactant (baseline demographic table). Could the randomization to CPAP vs. early surfactant have confounded the high/low saturation results (or, I guess, vice versa)? -dlp]

Major outcomes

The primary outcome, threshold retinopathy and/or death before discharge (retinopathy/death), did not differ between the lower and higher oxygen saturation groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; [redacted] Table 2). Death before discharge occurred in 130 of the 654 (20%) of the infants in the lower oxygen saturation group versus in 107 of the 662 (16%) of the infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; p=0.04). Comparable results were observed for both gestational age strata. Kaplan Meier Analysis indicated [redacted] **[We have not seen Figure 2 yet]** Mortality

in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). **[I made a new paragraph--dlp]**

Formatted: Font: Bold

Threshold retinopathy was decreased in the lower oxygen saturation targeted group (9 vs 18%; RR 0.51; CI 0.37, 0.71; p[redacted] **[We have to look at some other things here. Can't be left at one sentence ?? How about looking at the data to see if this sentence (entirely invented by me just now) is true? Those infants who developed threshold ROP as compared to those that did not were of younger GA, lower birthweight, where more often male, and White, but were similar when compared across the two saturation target groups... It would be quite interesting if these know ROP related characteristics were different across the saturation groups among those with the unfavorable outcome. --dlp]** Oxygen use at 36 weeks was decreased in the lower oxygen saturation group but bronchopulmonary dysplasia determined by the physiological oxygen saturation test at 36 weeks and the composite outcome of bronchopulmonary dysplasia/death did not differ between the treatment groups. Other pre-specified major outcomes did not differ significantly between the two treatment groups (Table 2).

Formatted: Highlight

Formatted: Font: Bold

Formatted: Font: Bold

The median oxygen saturation of both groups differed substantially but, as expected, there was substantial overlap (Figure 3). **[There is no comment here about this figure. and no legend. You have to at least say if the figure is data while infants were receiveing supplemental oxygen, or if the figure represents all saturation data, even when they are on room air. --- too incomplete. --dlp]** These data indicate that actual oxygen saturation levels are slightly higher than targets in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal

DISCUSSION

The recommended ranges of oxygen saturation targeting for very preterm infants have been determined from non-randomized studies, and restriction of oxygen supplementation is becoming a~~the~~ common practice.[3-5, 19] However, there was an increase in mortality when a restrictive oxygen supplementation was practiced in the 1950s and 1960s. Despite not being based on randomized controlled trials and the limited evidence of safety, lower oxygen saturation targeting has been increasingly adopted by units and physicians in an attempt to decrease ~~retinopathy of prematurity~~ROP. However, in this large multicenter randomized trial we found that even though lower oxygen saturation targeting reduced threshold ROP~~retinopathy~~, it also increased ~~the risk for~~ mortality.

This trial was not powered to examine a difference in mortality only between the two oxygen saturation groups. **[Isn't this first sentence incorrect? and if not incorrect, isn't it irrelevant? The significant difference was observed.]** ~~However, t~~This is the largest completed prospective multi-center randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results add to previous data raising the concern that oxygen restriction may increase mortality in very preterm infants. The infants in this trial were more immature than those of any previous trials of oxygen restriction and, thus, may have had a higher or lower susceptibility to the effects of lower oxygen

Formatted: Font: Bold

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

saturation targeting. The previous data on the increased mortality from oxygen restriction were from studies with lower levels of evidence rather than from randomized controlled trials.**[you had better reference the source of this statement or get ready to explain at lot.]** It is interesting and worrisome that the combined risk difference observed in the trials from the1950s was a 4.9% increase in mortality in the oxygen restricted group[1], **[why not reference the original paper instead of this review? -- reference provided in reference list for you Kinsey 1956]]** which is close to the 3.8% mortality increase in the lower targeted SpO2 group that was observed in our trial.

Formatted: Font: Bold

Formatted: Font: Bold

[This would be a good place to discuss the observation that the difference in mortality occurred after the first couple of weeks. Why would that be? You may have permission to speculate here... Fetal hemaglobin works better with low saturations? and as they get older adult hemaglobin levels go up? (maybe from transfusions). Or ..... other theories? --dlp]

Formatted: Font: Bold

Restriction of oxygenation controlled trials in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17, 20] However, these trials aimed for saturations of 91 to 94% and 89 to 94% in the lower oxygen saturation groups which are closer to the targets of the higher saturation arm in the current trial. The lower target of oxygen saturations or the use of the intervention starting at birth and continuing while oxygen supplementation was needed in the current trial may be related to the adverse outcome.

Recent meta-analyses of trials of restriction of oxygen supplementation based on trials conducted in the 1950s to the 1970s showed a large reduction in severe retinopathy (RR 0.19; CI 0.07, 0.50).[1,21] There

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

have not been other published randomized controlled trials of different oxygen targeting starting soon after birth to reduce retinopathy. However, results of most non-randomized studies show that lower oxygen saturation targeting reduces severe ROP~~retinopathy of prematurity~~. The current trial confirmed that lower oxygen targeting results in a large reduction of severe retinopathy.

In summary, lower oxygen saturation targeting did not significantly affect the combined outcome of threshold retinopathy/death but increased mortality and decreased threshold retinopathy. There are several ongoing trials across **[around?]** the world that address the same intervention tested in the current trial as well as a planned prospective meta-analysis.[22] These trials use the same algorithms for oxygen saturation targeting so their data will be easy to combine in a meta-analysis to determine short and long term effects of oxygen saturation targeting. **[While the following sentence is true, I don't know if it will be counterproductive or helpful to have it in the paper. I would be inclined not to use it. Instead empahsize the need for NDI. --dlp]** At the present time, it is important that these trials continue and that the investigators and the data safety and monitoring committees of these trials are aware of the results of the current trial so that appropriate decisions can be made regarding their interim analyses, completion of the trials, and dissemination of the data. The current trial raises the concern of adverse hospital outcomes due to oxygen saturation targeting in the 85 to 89% range. Neurodevelopmental assessments are being performed at 18-22 months corrected age. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years but at the present time, caution should be exercised regarding oxygen targeting in the low range for extremely premature babies, such as those tested in the current trial.

See the request below -- **Please send me an email by the end of the day with for the following:**

Rochester authorship (Dale has had significant responsibility for the ROP portion of the manual, forms, data collection, answering questions along the way for the trial, and general input into the ROP issues)

_____ Nirupama Laroia for both papers
_____ Nirupama Laroia for both papers + Dale Phelps for saturation manuscript
___x__ Nirupama Laroia for CPAP surf paper + Dale Phelps for saturation manuscript

Also, one other issue has come to my attention – Kurt Schibler is one the subcommittee but is only on one of the papers. Let me know if you both he and Vivek should appear in the mast head for the CPAP/surf paper

__x___ Kurt for both papers
_____ Kurt for only saturation paper

Subject: Saturation paper

Hi Wally,
Just wondering,
Did you intend to have me listed as a co-author on the saturation paper? I received your note sent to 'all authors'.

At present, I am listed only as the Center PI at Rochester in the Biolerplate.
Rochester's protocol PI for SUPPORT was Nirupama Laroia, so she is appropriately listed as the author from Rochester.

However, I have carried a significant responsibility for the ROP data form, training, instructions, monitoring, etc. for the ROP primary outcome -- I think we could justify adding me to the authors list.

Subject: PMA at final ROP status
Date: Monday, November 09, 2009 5:29:18 PM
Attachments: PMA at Final ROP Status- Graphs - 09NOV09.doc
PMA at final ROP status - 09NOV09.doc

Attached is information on the PMA of SUPPORT infants at the time they reached final ROP status. For all infants who met criteria for severe ROP, final ROP status was obtained by 53 weeks PMA, and the previous ROP exam was within three weeks of the final exam.

For infants who met criteria for final ROP status and did not have severe ROP, final ROP status was obtained by 55 weeks PMA for 91%. For 64% of those who did not have severe ROP, final status was obtained within 3 weeks of the previous exam, and for all but two infants, the exam previous to the one in which final ROP status was obtained was at <=55 weeks PMA. However, there were some cases where a lot more time passed between exams and where final status was obtained well after 55 weeks PMA, as you can see in the attached frequencies and graphs.

Do we need to draw any distinction between this "death" outcome and the death we will report as of the 18 month FU? There are a few infants who died before FU that are not counted as deaths here, and I'm sure there will be more.

I corrected a couple of typos in the abstract (attached). Also, I wonder if it will be confusing to refer to "oxygen use" in the text but BPD in the table? Finally, we are referring to "death before discharge" in the abstracts and manuscripts, but two of the deaths are cases that were actually "discharged home to die" per the center. It's a small distinction that might not merit any rephrasing of the outcome, but I just wanted to point it out. The two deaths are recorded on the NG03.

Hi Rose and all:

Enclosed is the O2 sat abstract. My title is more specific than Neil's. See which style you all prefer. I am concerned using Neil's because then both would have the same title.

I had to shorten the table as no more data would fit in.

Hi Rose
I will try
I am heading to Florida on the 11th
By the way I am unable to open the figures and tables - please resend
The ROP/Mortality findings are intriguuing
almost like the 50's when restricted oxygen reduced retinopathy but increased mortality
The follow up will be even more rvealing, especially if the low sat group have more problems - or did the low sats weed out the weak?
Be well
Av
PS Note still burning the candle at both ends

Hi Ed, Av, Jon and David,
You were included on the previous email and I am writing to ask a big favor.

We would like you to consider doing an internal review for these papers and providing me with written comments by 3 PM on 11/16. Let me know if your schedule permits. If you are not able to meet the time frame planned, let me know. There is urgency to submission of the papers.

Thanks in advance!!!
Rose

Hi,
Attached are the two papers in draft form for the SUPPORT Primary outcomes. As noted, there is an increase in death in the lower saturation group (20%) versus the higher saturation group (16%).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

This information is confidential and a plan is in place for DSMC communication with ongoing trials of oxygen saturation. If you are contacted by any investigators from other trials or elsewhere, do not share this information. If necessary, refer them to me.

The plan for submission is as follows:

November 16 – 4 PM – call for Steering committee and authors to discuss papers. In the meantime, feel free to send comments to Neil and Wally. The call in number is:
866-675-(b) (6) with passcode (b) (6)

If you are not going to be on the call, send comments in advance or designate someone to serve in your absence.

Immediately following the call, the manuscripts will be finalized for NICHD clearance and for submission to the New England Journal of Medicine.

Thanks in advance to everyone for all their hard work!!!
Rose

I agree with Marie that we should call it severe ROP or death, and then define severe ROP as threshold ROP or ROP requiring surgery.

Thanks

Abhik

Neil,

Here is your paper with updated numbers and my edits, as well as the three source tables I have produced before, now with adjusted p-values and RRs where appropriate.

Will there also be a table showing the primary outcomes? Right now the variables covered in the text and tables don't seem to match completely.

I saw the messages about adding a decimal to the percentages, but not before I had run this version. I will re-run the CPAP and SpO2 paper tables tomorrow with the decimal.

Marie

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilator strategy. Infants randomized to surfactant were to be intubated and receive ~~d~~ surfactant within 60 min minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while ~~in the NICU and~~ receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was ~~49~~8.7% in the CPAP group versus 54.1% in the surfactant group, (RR 0.91, 95% CI 0.8~~3~~2, 1.0~~1~~0, p=0.07~~2~~6 when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (243.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.03). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011~~9~~) and fewer required intubation or post natal steroids for BPD, (p<.001).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Conclusions: The use of CPAP in such infants is an effective evidence based alternative to intubation and surfactant.

Introduction:

At the present time, there is no agreement as to the optimal approach to respiratory support for the extremely low birth weight (ELBW) infant following delivery. Positive End Expiratory Pressure (PEEP) has been shown to be of benefit in maintaining functional residual capacity (FRC), and continuous positive airway pressure appears beneficial during cardiopulmonary resuscitation[1]. Gregory et al in 1971 first demonstrated that the use of CPAP started at approximately 5.9 hours (+12.4hrs) for their infants < 1500 gm at birth, improved oxygenation[2] in newborn infants with respiratory distress; these observations were followed by prospective studies that demonstrated improved survival in premature infants treated with early CPAP[3]. A review of prospective studies evaluating early (not delivery room) CPAP in the pre-surfactant, pre-antenatal steroid era found that early CPAP improved survival overall and for infants greater than 1500 gm, and was associated with increased pneumothoraces.[4] A more recent review of prophylactic CPAP started in the delivery room reviewed only 2 available trials and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

found no significant difference between the CPAP and conventionally managed infants and noted a trend to increased adverse outcomes for the CPAP treated infants.[5]

There is substantial retrospective evidence suggesting a benefit for early CPAP for preterm infants with RDS in experiences from both the US and other countries.[678] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following the initiation of early CPAP treatment.[91011]

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[1213] ~~The surfactant trials preceeded widespread use of antenatal corticosteroids to promote lung maturation.~~ Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI).[14] However, the surfactant trials preceded widespread use of antenatal corticosteroids to promote lung maturation and the placebo groups did not received mechanical ventilation which could be injurious.

The recent COIN trial randomized 610 infants from 25 weeks 0 days to 28 weeks 6 days gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[15] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group ~~(9.1~~(9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

with the findings of an earlier meta analysies[44], and a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) ~~with~~) with no statistically significant difference in death or BPD at 36 weeks.

Formatted: Font: 12 pt, Superscript

In view of the current interest in the use of early CPAP and the lack of prospective comparisons of this approach with the evidence based intervention of prophylactic or early surfactant, the SUPPORT Trial~~study~~ was designed to compare these approaches for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design, and the results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324).This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters. (already stated)~~These results will be separately reported~~.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a protocol driven limited ventilator strategy in infants of 24 to 2~~8~~ weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born at a randomizing center without known malformations, for whom a decision had been made to provide full resuscitation, -and parental consent had been obtained. The infants were randomized within each center to 2 gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used at all sites for the delivery room administration of CPAP. CPAP or ventilation with PEEP both at a recommended 5 cm H_2O was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU using the T-piece ~~resuscitator or~~resuscitator or equivalent device and a face mask or nasal prongs. CPAP infants were not to be intubated for surfactant only in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications (need ref) including failure to respond to positive pressure ventilation (PPV) with evidence of continuing cyanosis or bradycardia, the need for chest compressions, the need to administer intratracheal medications, or other situations in which the resuscitation team determined that surfactant is urgently required.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

NICU management: ~~Intubation was allowed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery. While intubation was never required by protocol,~~ CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 ≥ 88% for one hour, an arterial $PaCO_2$ > 65 torr ~~documented on a single blood gas within one hour of intubation~~, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean airway pressure (MAP) < 10 cm H2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations CPAP infants were treated using NICU ~~standardpractice~~standard practice.

Surfactant Arm: All infants were to be intubated within 1 hour of life and receive surfactant, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30 An FiO2 ≤ 35 with a SpO2 ≥88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate ≤ ~~15 bpm~~15 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and ~~be~~ hemodynamically ~~stable with~~stable without

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

~~no~~ evidence of clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms of the trial intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, and thus multiples, were randomized to the same arm of the trial.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, (using the NRN occurrence of death or survival with BPD of 67% using the year 2000 data)~~, and~~, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months (using the NRN occurrence of NDI of 61~~% using~~% using year 2000 data) by 10%. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1312 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the 2 factorial arms.

Comment [MG1]: I believe the SpO2 paper says 1310. They should agree.

In addition there was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which required an attempt at oxygen withdrawal for infants who

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

required < 30% oxygen at 36 weeks and assigned a diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support. [1617]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each g~~G~~roup who ~~developed their respective outcome measure of survival~~survived to 36 weeks PMA without BPD ~~at 36 weeks~~. ~~Adjustment was performed as pre-specified for gestational age stratum, center and familial clustering~~ Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. Continuous outcomes were analyzed using mixed effects linear models. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age stratum, center and familial clustering. A two-sided P value of less than 0.05 was considered statistically significant.

Formatted: Font: 12 pt

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. {Lan-DeMets spending functions with Pocock or {O'Brien-Fleming} boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and a combination of any of the above events.

Comment [MG2]: Also chest compressions and/or epinephrine in the DR, pulmonary hemorrhage, and nasal breakdown requiring the discontinuation of nasal prongs.

The study was approved by Human Subjects Committees at all participating sites and RTI, the NRN data center that managed and analyzed all the data, and parental consent for participation in the trial was required before delivery

Results:

There were 1316 infants enrolled in this trial from Feb 2005 through ~~to Mar 1~~Feb ~~2009 -~~ 2009. Enrollment ~~The trial~~ was temporarily suspended by the DSMB because of concerns regarding the oximetry data in November 2005 but after a complete review the trial was continued in February 2006 with no protocol changes. The patient descriptive information for the CPAP versus Surfactant arms is shown in Table 1. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, Apgar scores or race between the 2 treatment groups. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant.

In the delivery room, 65.7~~6~~% of the CPAP infants received positive pressure ventilation compared with 92.9~~3~~% of the surfactant infants, and surfactant was given to 14.1% of the CPAP versus 51.4% of the surfactant group; 67.1% of the CPAP infants received surfactant in the delivery room or NICU, compared to 98.9% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34.4% of CPAP infants compared with 93.4% of surfactant infants, $p<0.001$, Table 2.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post menstrual~~conceptional~~ age was non-significantly reduced for the CPAP group compared with the Surfactant group, 48.7~~9~~% versus 54.1%, (RR 0.91, 05% CI 0.83~~2~~, 1.01~~0~~, p=0.06~~0~~72) when adjusted for gestational age, center and familial clustering as prespecified. Death during the hospitalization was 43.2% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata,~~,~~ 243.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.034, Table 4. Overall, t~~T~~here was a non-significant reduction in the occurrence of BPD using the need for supplemental oxygen, 40.2% vs 44.3%, RR 0.94~~3~~, 95% CI 0.82, 1.06. Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39.2% vs 40.6~~1~~%, RR 0.99, 95% CI 0.87, 1.14), and a non-significant reduction in the occurrence of death or Physiologic BPD at 36 weeks in the CPAP group, (47.8% vs 51.0%, RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room, ~~nor any differences in~~ length of stay, ~~or~~ days of oxygen for survivors, or discharge on oxygen~~.~~ (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011~~9~~). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. Nearly a~~A~~ll infants in the Surfactant arm were intubated (99.7%), compared with 83.1% of the CPAP infants who required intubation during their nursery course, (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants, 7.2% vs 13.2%, p<0=.00105). ~~The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative~~

~~Group[18] was non- significantly reduced in in the CPAP compared to the surfactant infants, (23% vs 31%, RR=0.75(0,54, 1.05)~~

Strata Results: 24 – 25 weeks Gestation

There were more non-Hispanic black infants and Hispanic infants in the CPAP group compared with the Surfactant group. The differences are shown in Table 4 (24-25 wk Strata). CPAP infants had a significantly lower mortality while hospitalized 243.9% vs 32.1%, RR=0.74, 95% CI 0.57, 0.98, p=0.034. There was a significantly higher exposure to postnatal steroids for BPD, 20.5% vs 13.0%, p=0.023 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata. The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[19] or need for surgical intervention for ROP was non-significantly reduced in the CPAP compared to the surfactant infants, (23.3 vs 31.4%, RR=0.75, 95% CI 0.54, 1.05).

Comment [MG7]: Race is not in tab le

Comment [MG8]: Not in table

Comment [MG9]: These numbers were reported above but are for the 24-25 week GA stratum

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups, 10.80% vs 10.21%. The CPAP infants required fewer days of oxygen, ~~40.6~~44.0 vs ~~47.1~~49.5, p=0.035~~1~~, and lesser days of mechanical ventilation, ~~11.3~~13.7 vs ~~14.9~~16.7, p=0.085~~1~~, and fewer infants received postnatal steroids for BPD, 2.9~~3~~% vs ~~8~~7.9%, p=<0.008~~1~~.

Comment [MG10]: Non-significant

Discussion:

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The SUPPORT Ttrial is the first prospective randomized multicenter trial to compare early CPAP with early surfactant ~~given within an hour of life~~ in ELBW infants and the only prospective randomized trial comparing CPAP to any other intervention~~other outcome~~ that enrolled infants of 24 weeks gestation. In a preliminary study we found that 100% of infants of 23 weeks gestation required intubation in the DR, and thus decided that such infants would be unlikely to be successfully treated with CPAP alone following delivery.[20] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[21]

Our trial~~study~~ differs from the recently reported COIN trial[15~~15~~] in that we randomized all eligible ELBW infants of consenting families irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven limited ventilator strategy with infants who ~~all~~ were to received surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold approach for intubation and the initiation of mechanical ventilation, and the current practice of a number of NRN units.[6,7] We believed that testing this complete approach would provide a more relevant result as most units currently using early CPAP also tend to have a higher threshold for intubation.

Formatted: Font: 12 pt, Superscript

Our study has demonstrated that intent to treat with early CPAP and protocol driven limited ventilator strategy ~~when compared~~compared to ~~with~~ surfactant given within 1 hour of birth was associated with a non-significant decrease in death ~~or survival with~~by 36 weeks PMA or

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

BPD as defined by the need for oxygen at 36 weeks from 54.1% to 498.7%. We also noted a ~~very~~ significant 8.2% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.25 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that this lower incidence of death in these infants along ~~with reductions~~with reductions in BPD, ~~ROP, significantly,~~ significantly decreased durations of mechanical ventilation ~~and oxygen~~, a decreased need for intubation and exposure to post natal steroids in the overall CPAP ~~group without~~group without any increase in adverse neonatal ~~outcomes represents~~outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

We prospectively identified a number of safety outcomes that we chose to follow as investigators. These included the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks~~, initially defined as pneumothoraces but later altered to include pulmonary interstitial emphysema, pneumomediastinum and pneumopericardium~~. We did not find an increase in airleaks in the first 14 days of life with ~~the use of~~randomization to early CPAP at 5 cm H2O compared to ~~the use of~~ early surfactant.

The SUPPORT Trial~~study~~ was a factorial design with each infant randomly ~~receiving 2~~receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we did prospectively agree to evaluate such interactions and none were found. Both arms of the study were

adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Conclusions:

Compared with ~~the use of~~randomization to surfactant within 1 hour of birth, ELBW infants between 24 and 27 6/7ths weeks gestation at birth assigned to treatment~~ed~~ with CPAP and a protocol driven limited ventilator strategy have a non significant decreased incidence of death ~~or survival with~~by 36 weeks PMA or BPD based on the need for oxygen at 36 weeks ~~PCA~~ PMA with no demonstrable increase in any adverse neonatal outcomes. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

Table 2. Other outcomes for CPAP vs. Surfactant

Characteristic	Category	CPAP (N=663)	Surfactant (N=653)	Relative Risk for CPAP vs. Surfactant (95% CI)	Adjusted P-value
Death in the first week		6.0% (40/663)	6.0% (39/653)	0.99 (0.64, 1.53)	0.9575
Total LOS any hospital (survivors only) (NG03, NG05)	Mean±StdErr (N=1075)	104.8 ± 2.0	106.2 ± 2.0		0.5967
LOS in NRN hospital (survivors only) (NG03, NG05)	Mean±StdErr (N=1079)	101.4 ± 2.0	101.5 ± 2.0		0.9444
Days on supplemental oxygen (survivors to NG03 status only) (NG07)	Mean±StdErr (N=1098)	62.2 ± 1.6	65.3 ± 1.6		0.1215
Days on mechanical vent (HFV & CV) (survivors to NG03 status only) (NG07)	Mean±StdErr (N=1098)	24.8 ± 1.0	27.7 ± 1.1		0.0287
DOL of last supplemental oxygen through 36 weeks PMA (survivors to NG03 status only) (SUPP05, SUPP11)	Mean±StdErr (N=1082)	57.5 ± 0.9	58.8 ± 0.9		0.2240
Days on CPAP (survivors to NG03 status only) (NG07)	Mean±StdErr (N=1098)	17.3 ± 0.6	16.8 ± 0.6		0.4713
Days on nasal SIMV (survivors to NG03 status only) (NG07)	Mean±StdErr (N=1098)	3.4 ± 0.3	3.7 ± 0.3		0.4552
Discharge on oxygen (NG03 or NG05)		22.2% (122/550)	23.9% (124/519)	0.98 (0.8, 1.2)	0.8202
Alive and off MV (HFV/CV) at 7 days (NG07 or SUPP05)		55.3% (362/655)	48.8% (318/652)	1.14 (1.03, 1.25)	0.0111
Pneumothorax (NG03 or SUPP08)		8.1% (54/663)	5.5% (36/653)	1.46 (0.96, 2.21)	0.0786
Any air leak in first 14 days (SUPP08)		6.8% (45/663)	7.4% (48/653)	0.89 (0.6, 1.32)	0.5553
Medical or surgical NEC (NG03)		12.7% (83/654)	9.9% (63/636)	1.25 (0.92, 1.71)	0.1469
PDA requiring surgery (NG03)		11.2% (73/653)	10.7% (68/636)	1 (0.73, 1.36)	0.9937
IVH grade 3-4 (NG03)		14.3% (92/642)	11.5% (72/628)	1.26 (0.94, 1.68)	0.1223
PVL (NG03 or MRI01)		4.4% (28/643)	4.1% (26/629)	1.09 (0.63, 1.88)	0.7538
Death or PVL (NG03 or MRI01)		20.2% (134/663)	22.5% (147/653)	0.9 (0.74, 1.11)	0.3185
Postnatal steroids for BPD (NG03)		7.2% (47/649)	13.2% (83/631)	0.57 (0.41, 0.78)	0.0005
Postnatal steroids after DOL 21 (SUPP09)		17.3% (114/659)	22.9% (149/652)	0.75 (0.61, 0.92)	0.0069
Intubated in DR (SUPP03)		34.4% (227/660)	93.4% (609/652)	0.37 (0.34, 0.42)	<0.0001
Intubated in DR or NICU in first 14 days (SUPP03, SUPP04)		76.9% (508/661)	99.5% (649/652)	0.77 (0.74, 0.8)	<0.0001
Any intubation (SUPP03, SUPP04, SUPP05, SUPP05a, SUPP07)		83.1% (551/663)	99.7% (651/653)	0.83 (0.8, 0.86)	<0.0001

Rose
I would go with the following:
Nirupama Laroia for both papers + Dale Phelps for saturation manuscript
Ed and Vivek on the CPAP/surfactant
Kurt and Vivek on the saturation paper.
Tx, AL

Importance: High

Kurt has proposed an alternative for the CPAP/surf paper. As many of you are likely to recall, Ed Donovan organized the SUPPORT training and the video in 2004. Let me know if ED and Vivek can appear on the CPAP/surf paper.

Thanks
Rose

Importance: High

Hi Rose,
Personally, I would like to advocate that Ed Donovan and Vivek Narendran both be listed as Cincinnati authors on the CPAP Surfactant manuscript since Ed and Vivek did a lot to move forward the study up front and Vivek was instrumental during the trial. (Ed did a lot with initial start up and education, hosting the training, producing the training video, and was the Cincinnati PI at the beginning of the study). I would like to be listed as the author from Cincinnati on the Oxygen Saturation.
Thanks,
Kurt

Subject: Saturation paper

Hi Wally,

Just wondering,

Did you intend to have me listed as a co-author on the saturation paper? I received your note sent to 'all authors'.

At present, I am listed only as the Center PI at Rochester in the Biolerplate.

Rochester's protocol PI for SUPPORT was Nirupama Laroia, so she is appropriately listed as the author from Rochester.

However, I have carried a significant responsibility for the ROP data form, training, instructions, monitoring, etc. for the ROP primary outcome -- I think we could justify adding me to the authors list.

I corrected a couple of typos in the abstract (attached). Also, I wonder if it will be confusing to refer to "oxygen use" in the text but BPD in the table? Finally, we are referring to "death before discharge" in the abstracts and manuscripts, but two of the deaths are cases that were actually "discharged home to die" per the center. It's a small distinction that might not merit any rephrasing of the outcome, but I just wanted to point it out. The two deaths are recorded on the NG03.

Hi Rose and all:

Enclosed is the O2 sat abstract. My title is more specific than Neil's. See which style you all prefer. I am concerned using Neil's because then both would have the same title.

I had to shorten the table as no more data would fit in.

Title: Randomized Trial of Oxygen Saturation Targets in Premature Infants-the SUPPORT Trial

W A Carlo, MD[1], N N Finer, MD[2] and on behalf of the SUPPORT Subcommittee for the NICHD Neonatal Research Network. [1]University of Alabama at Birmingham, Birmingham, Alabama, United States and [2]University of California San Diego, San Diego, California, United States.

Background: Recent non-randomized studies suggest that the incidence of retinopathy of prematurity (ROP) decreases in premature infants with oxygenation levels lower than previously maintained. However, it is important to determine if lower oxygen saturation targets reduce ROP without increasing adverse outcomes

Objective: To test the hypothesis that a lower oxygen saturation target decreases severe ROP and/or death in extremely premature infants.

Design/Methods: 1316 infants of 24 0/7 to 27 6/7 weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95% using masked oximeters ~~or~~ as part of a 2x2 factorial trial. The primary outcome was a composite of severe ROP (Type 1 threshold ROP/surgery/bevacizumab) and/or death.

Results: Severe ROP/death did not differ between the oxygen saturation target groups (Table; adjusted for stratification factors: study center, gestational age group, and familial clustering). Severe ROP was decreased (P<0.001) in the lower oxygen saturation target group but death was more frequent (P=0.0415, Table). Oxygen use at 36 weeks significantly decreased in the lower oxygen saturation target group but oxygen use by the physiologic definition or oxygen use at 36 weeks/death did not decrease. Other outcomes did not differ between the groups (Table).

Conclusions: Lower oxygen saturation (85-89%) targets did not significantly decrease the combined outcomes of severe ROP/death but resulted in an increase in mortality that partially offset a decrease in severe ROP. The increased mortality is of concern as lower saturation targeting is increasingly being advocated because it has short term ROP benefits.

	Lower O2 Saturation Group n/N (%)	Higher O2 Saturation Group n/N (%)	Adjusted Relative Risk1 (95% CI)
Severe ROP/death	170/605 (28.3)	198/616 (32.1)	0.90 (0.76, 1.06)
Severe ROP	43/483 (8.9)	95/514 (18.5)	0.51 (0.37, 0.71)
Death before discharge	130/654 (19.9)	107/662 (16.2)	1.27 (1.01, 1.60)
Bronchopulmonary dysplasia (physiologic) at 36 weeks	205/540 (38.0)	237/568 (41.7)	0.92 (0.81, 1.05)
Intraventricular hemorrhage, grade 3 or 4	83/630 (13.2)	81/640 (12.7)	1.06 (0.80, 1.40)
Necrotizing enterocolitis, stage ≥ 2	76/641 (11.9)	70/649 (10.8)	1.11 (0.82, 1.51)

Hi Rose and all:

Enclosed is the O2 sat abstract. My title is more specific than Neil's. See which style you all prefer. I am concerned using Neil's because then both would have the same title.

I had to shorten the table as no more data would fit in.

Wally

Title: Randomized Trial of Oxygen Saturation Targets in Premature Infants-the SUPPORT Trial

W A Carlo, MD[1], N N Finer, MD[2] and on behalf of the SUPPORT Subcommittee for the NICHD Neonatal Research Network. [1]University of Alabama at Birmingham, Birmingham, Alabama, United States and [2]University of California San Diego, San Diego, California, United States.

Background: Recent non-randomized studies suggest that the incidence of retinopathy of prematurity (ROP) decreases in premature infants with oxygenation levels lower than previously maintained. However, it is important to determine if lower oxygen saturation targets reduce ROP without increasing adverse outcomes

Objective: To test the hypothesis that a lower oxygen saturation target decreases severe ROP and/or death in extremely premature infants.

Design/Methods: 1316 infants of 24 0/7 to 27 6/7 weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95% using masked oximeters or part of a 2x2 factorial trial. The primary outcome was a composite of severe ROP (Type 1 threshold ROP/surgery/bevacizumab) and/or death.

Results: Severe ROP/death did not differ between the oxygen saturation target groups (Table; adjusted for stratification factors: study center, gestational age group, and familial clustering). Severe ROP was decreased (P<0.001) in the lower oxygen saturation target group but death was more frequent (P=0.045, Table). Oxygen use at 36 weeks significantly decreased in the lower oxygen saturation target group but oxygen use by the physiologic definition or oxygen use at 36 weeks/death did not decrease. Other outcomes did not differ between the groups (Table).

Conclusions: Lower oxygen saturation (85-89%) targets did not significantly decrease the combined outcomes of severe ROP/death but resulted in an increase in mortality that partially offset a decrease in severe ROP. The increased mortality is of concern as lower saturation targeting is increasingly being advocated because it has short term ROP benefits.

	Lower O2 Saturation Group n/N (%)	Higher O2 Saturation Group n/N (%)	Adjusted Relative Risk1 (95% CI)
Severe ROP/death	170/605 (28.3)	198/616 (32.1)	0.90 (0.76, 1.06)
Severe ROP	43/483 (8.9)	95/514 (18.5)	0.51 (0.37, 0.71)

I agree with Marie that we should call it severe ROP or death, and then define severe ROP as threshold ROP or ROP requiring surgery.

Thanks

Abhik

Wally,

Here are my edits for the PAS abstract. I am still concerned about just calling the primary outcome threshold ROP or death, as some of our infants who received surgery for ROP did not have a prior exam recorded with threshold ROP. My edits reflect one possible way of rephrasing the outcome.

Thanks,
Marie

Subject: Oxygen Saturation paper for your comments.

Dear SUPPORT Subcommittee members:

Enclosed is a draft of the oxygen saturation paper for your comments. I need everyone's comments before we can submit to the Publications Subcommittee and the whole Steering Committee which gets it at the same time. I am also enclosing the first draft of the PAS abstract which is currently slightly above the word limit.

Any air leak in first 14 days (SUPP08)	51/654 (7.8)	42/662 (6.3)	1.23 (0.83, 1.83)	0.2941
Postnatal steroids for BPD (NG03)	61/636 (9.6)	69/644 (10.7)	0.91 (0.67, 1.24)	0.5449
Postnatal steroids after DOL 21 (SUPP09)	123/650 (18.9)	140/661 (21.2)	0.91 (0.74, 1.12)	0.3850

Relative risks are adjusted for GA stratification, center and familial clustering.
Centers with fewer than 10 infants enrolled and those with an incidence of zero for the outcome in question were combined with the geographically closest site for RR calculation.
Data from NG03 exclude infants who died in the first 12 hours.

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Running head: Oxygen saturation and outcomes of prematurity

Key words: prematurity, extremely low birth weight infant, neonatal mortality, oxygen toxicity

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95%. The primary outcome was a composite of threshold retinopathy of prematurity and/or death.

Results

Threshold retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28.3 vs 32.1%; RR 0.90; CI 0.76, 1.06; adjusted p-value = ~~).~~ 0.205). Death was more frequent in the lower oxygen saturation target group (19.9~~20~~ vs 16.2%; RR 1.27; CI 1.01, 1.60; adjusted p-value = 0.~~)~~.041) while threshold retinopathy occurred less often in these infants (8.9 vs 18.5%; RR 0.51; CI 0.37, 0.71; adjusted p-value= ~~).~~0.0001).

Conclusions

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcome of threshold retinopathy/death but resulted in an increase in mortality that partially offset a decrease in threshold retinopathy. The increased mortality is of concern as lower saturation targeting is increasingly

Comment [MG1]: 3 of the randomized infants were actually 28 0/7 weeks GA

Comment [MG2]: Do we need to be specific and say threshold or ROP surgery? Not all infants who had surgery for ROP also had an exam with threshold in our data.

Comment [MG3]: These numbers include 13 infants who died (6 who had ROP and 7 who did not). Do you want me to remove them so it's strictly ROP among survivors?

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] However, in subsequent years, the practice of restricting oxygen supplementation was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6, 7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy[12], and other morbidities. Although a multicenter study [13] could not determine an association between oxygen levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations of lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3,4,5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery was higher in infants cared for in neonatal intensive care units with maximum target oxygen saturation $\geq$ 92% (3.3 $\pm$ 0.3 versus 1.4 $\pm$ 0.2%) or $\geq$ 98% (5.6 $\pm$ 1.1 versus 3.1 $\pm$ 0.3%).[5] The incidence of severe retinopathy requiring ablation therapy was 27% in units where target saturations were 88 to 98% and only 6% in units where the target was 70 to 90% in a retrospective study comparing outcomes at five neonatal intensive care units.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

to 95% resulted in a substantial reduction in retinopathy.[4, 15, 16] However, actual oxygen saturations achieved were not reported. Furthermore, mortality and neurodevelopmental outcomes were not reported. While data from these recent prospective observational studies, retrospective studies, or controlled but not randomized studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease the incidence of retinopathy of prematurity, there is no conclusive evidence that these oxygenation levels do so without an increase in serious adverse effects, including the possibility of increased risk of death with lower oxygenation as previously reported.

We conducted a 2 x 2 factorial-design multicenter randomized trial of oxygen saturation targeting and protocol-driven limited ventilator strategy. The oxygen saturation part of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of threshold retinopathy of prematurity or death among infants of 24 to 27 weeks gestational age at birth. The ventilation part of this factorial design trial was used to control for the ventilatory approach and test other hypotheses and will be reported separately.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at RTI, the independent data coordinating center, approved the trial. Written informed consent was obtained from the parent or guardian of each participant before delivery.

Patients

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation for which a decision had been made to provide full resuscitation were eligible for enrollment at birth. Outborn infants and those known to have major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of double-sealed opaque envelopes to oxygen saturation targeting of 85 to 89% or 91 to 95% (the lower and higher oxygen saturation target groups, respectively) using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88 to 92% for these oxygen ranges, with an offset of 3% (Massimo Radical Set Pulse Oximeter, Irvine, CA) as previously used to separate oxygen saturations in premature infants.[17] Thus, for example, an oxygen saturation display of 92% would correspond to an actual oxygen saturation of 89% and 95% in the 85-89% and 91-95% target groups, respectively. The oxygen saturation values displayed reverted to actual values when less than ~~85~~84% or higher than ~~95~~96%, the levels of alarm setting recommended in the protocol. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours. Infants weaned to room air but who subsequently received oxygen supplementation before 36 weeks post-menstrual age were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinical, not the research staff. Reports of displayed data by clinical center were provided quarterly for feedback on targeting performance. For the ventilation part of this 2 by 2

Comment [MG4]: The offset was 3% in the target ranges, but at points above and below the target ranges where the display values were transitioning back to "actual" values the offset was not necessarily 3%

Comment [MG5]: A display value of 84 in the high target group corresponds to actual values of 84-87. Below 84 the display values correspond to actual values in both treatment groups.

Comment [MG6]: A display value of 96 in the low target group corresponds to actual values of 93-96. Above 96 the display values correspond to actual values in both treatment groups.

factorial design trial, participants were also randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilation strategy.

Assessments

Research nurses recorded all data using standardized definitions included in the trial Manual of Operations. Data were collected until discharge except for retinopathy. The primary outcome was death before discharge and/or threshold retinopathy or surgery or Avastin treatment for ROP. Threshold retinopathy of prematurity (New Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18]) was coded if any of the following findings were present ~~up to 55 weeks post-menstrual age~~:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic interventions defined as any of the following: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, vitrectomy, and bevacizumab (Avastin).

Other outcomes recorded included only predefined clinical diagnoses and potential adverse events.

Statistical analysis

The primary analysis of categorical outcomes for the oxygen saturation arm of this factorial trial was a generalized estimating equation (GEE) model that used robust Poisson regression to produce adjusted relative risks (RR) comparing incidence rates for infants in each treatment arm who developed the

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

primary outcome. Continuous outcomes were analyzed using mixed effects linear models. Survival analysis using Cox regression produced a hazard ratio (HR) for comparing mortality in the low and high oxygen saturation groups. ~~The model produces relative risk estimates~~ GEE, mixed effect and survival models were adjusted for stratification by center and gestational age as well as for familial clustering due to randomization of multiple births to the same treatment arm. A median actual oxygen saturation value while on oxygen supplementation was determined for each infant to compare the effect of targeting an actual oxygen saturation value between treatment arms.

An absolute difference of 10% between the two treatment groups was considered clinically important. The sample size calculations were based on the rate of death or threshold retinopathy of 50% in the Neonatal Research Network from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or neurodevelopmental impairment at 18-22 months corrected age). Based on an intracluster correlation of 0.12 in this outcome, the sample size was increased by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because this introduced a clustering effect into the design. The required sample size was increased by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the two factorial arms.

Intent-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. A two-sided adjusted p-value of less than 0.05 was considered to be statistically significant. Analyses did not include adjustment for multiple comparisons. An independent Data Safety and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at ~25%, 50%, and 75% of planned enrollment. In addition, the Data Safety and Monitoring Committee, upon request of the investigators, evaluated the oxygen saturation data after enrollment of ~~——~~247 infants to evaluate compliance with the protocol. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included **death, pneumothorax, intraventricular hemorrhage,** and a combination of any of the above events.

Comment [MG7]: Also need for chest compressions and/or epinephrine in the DR, pulmonary hemorrhage, and nasal breakdown requiring the discontinuation of nasal prongs.

RESULTS

1316 infants were enrolled between ~~January~~ February ~~2004~~ 2005 and ~~March~~ February 2009 (Figure 1). Enrollment was temporarily paused after evaluation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and Human Development Director because of concerns regarding compliance with oxygen saturation targets. Separate analysis of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns, and continued enrollment was approved.

The baseline characteristics of the lower saturation group and the higher saturation group were similar (Table 1).

Major outcomes

The primary outcome, threshold retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28.3 vs 32.1%; RR 0.90; CI 0.76, 1.06; ~~p=~~adjusted p-value

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

0.~~-~~.205; Table 2). Death before discharge occurred in 130 of the 654 (19.9~~20~~%) of the infants in the lower oxygen saturation group versus in 107 of the 662 (16.2%) of the infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; p=0.041). Comparable results were observed for both gestational age strata. ~~Kaplan Meier Analysis indicated~~ Cox regression analysis indicated that there was a significantly higher hazard of death in the lower oxygen saturation group (HR 1.32; CI 1.01, 1.72; p= 0.045) (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). **Threshold retinopathy** or surgical intervention for ROP **was decreased in the lower oxygen saturation targeted group** (8.9 vs 18.5%; **RR 0.51; CI 0.37, 0.71; p=0.**~~-~~).~~-~~.0001). Oxygen use at 36 weeks PMA was decreased in the lower oxygen saturation group but bronchopulmonary dysplasia determined by the physiological oxygen saturation test at 36 weeks PMA and the composite outcome of bronchopulmonary dysplasia/death by 36 weeks PMA did not differ between the treatment groups. Other pre-specified major outcomes did not differ significantly between the two treatment groups (Table 2).

Comment [MG8]: These numbers include 13 infants who died (6 who had ROP and 7 who did not). Do you want me to remove them so it's strictly ROP among survivors?

The median oxygen saturation of both groups differed substantially but, as expected, there was substantial overlap (Figure 3). These data indicate that actual oxygen saturation levels are slightly higher than targets in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Table 3). Other measures of resource utilization did not differ as well.

DISCUSSION

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The recommended ranges of oxygen saturation targeting for very preterm infants have been determined from non-randomized studies, and restriction of oxygen supplementation is becoming the common practice.[3-5, 19] However, there was an increase in mortality when a restrictive oxygen supplementation was practiced in the 1950s and 1960s. Despite not being based on randomized controlled trials and the limited evidence of safety, lower oxygen saturation targeting has been increasingly adopted by units and physicians in an attempt to decrease retinopathy of prematurity. However, in this large multicenter randomized trial we found that even though lower oxygen saturation targeting reduced threshold retinopathy or the need for surgical intervention for ROP, it also increased the risk for mortality.

This trial was not powered to examine a difference in mortality only between the two oxygen saturation groups. However, this is the largest completed prospective multi-center randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results add to previous data raising the concern that oxygen restriction may increase mortality in very preterm infants. The infants in this trial were more immature than those of any previous trials of oxygen restriction and, thus, may have had a higher susceptibility to the effects of lower oxygen saturation targeting. The previous data on the increased mortality from oxygen restriction were from studies with lower levels of evidence rather than from randomized controlled trials. It is interesting and worrisome that the combined risk difference observed in the trials from the1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.87% mortality increase in the lower targeted SpO2 group that was observed in our trial.

Restriction of oxygenation controlled trials in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17, 20] However, these trials aimed for

saturations of 91 to 94% and 89 to 94% in the lower oxygen saturation group which are closer to the targets of the higher saturation arm in the current trial. The lower target of oxygen saturations or the use of the intervention starting at birth and continuing while oxygen supplementation was needed in the current trial may be related to the adverse outcome.

Recent meta-analyses of trials of restriction of oxygen supplementation based on trials conducted in the 1950s to the 1970s showed a large reduction in severe retinopathy (RR 0.19; CI 0.07, 0.50).[1,21] There have not been other randomized controlled trials of different oxygen targeting starting soon after birth to reduce retinopathy. However, results of most non-randomized studies show that lower oxygen saturation targeting reduces retinopathy of prematurity. The current trial confirmed that lower oxygen targeting results in a large reduction of severe retinopathy.

In summary, lower oxygen saturation targeting did not affect the combined outcome of threshold retinopathy or surgical intervention/death but it increased mortality and decreased threshold retinopathy or surgical intervention. There are several ongoing trials across the world that address the same intervention tested in the current trial as well as a planned prospective meta-analysis.[22] These trials use the same algorithms for oxygen saturation targeting so their data will be easy to combine in a meta-analysis to determine short and long term effects of oxygen saturation targeting. At the present time, it is important that these trials continue and that the investigators and the data safety and monitoring committees of these trials are aware of the results of the current trial so that appropriate decisions can be made regarding their interim analyses, completion of the trials, and dissemination of the data. The current trial raises the concern of adverse hospital outcomes due to oxygen saturation targeting in the 85

Comment [MG9]: Is this still true after some trials have switched to the new oximeter algorithm?

to 89% range. Neurodevelopmental assessments are being performed at 18-22 months corrected age. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years but at the present time, caution should be exercised regarding oxygen targeting in the low range for extremely premature babies, such as those tested in the current trial.

Telephone 301.230.4640 ▪ Fax 301.230.4647 ▪ www.rti.org

Hello _____:

I am writing to you on behalf of the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), part of the U.S. National Institutes of Health, and the Data Safety and Monitoring Committee (DSMC) for the NICHD Neonatal Research Network.

The SUrfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants (SUPPORT Trial) is a prospective, randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network in the United States of America. One of the factorial arms of this trial compares a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant no longer requires ventilatory support or oxygen. The oxygen saturation monitoring portion of the study is designed to allow a blinded comparison of 2 different SpO2 levels using specially designed pulse oximeters that are calibrated to provide actual SpO2 values when the SpO2 is < 85% and > 95%. The primary outcome for this portion of the trial is survival free of severe retinopathy of prematurity (ROP), severe ROP being defined as threshold ROP and/or the need for surgical intervention.

This trial is now complete, and after their final planned look at the data, the independent DSMC for this trial recommended the sharing of some of this data with you, in your capacity as DSMC Chair for an ongoing randomized clinical trial that is using a similarly designed oximeter to compare a lower SpO2 range with a higher SpO2 range in a similar population of extremely premature babies. This data and an accompanying report are attached with this communication for your consideration as you review interim safety information for the trial you are monitoring.

Please note that since the study investigators are currently working on preparing final manuscripts for publishing the results of this trial, **the data that you are receiving should be treated with the strictest confidence** and not shared outside your DSMC, or with the investigators of the trial you are monitoring.

Sincerely

Abhik Das, Ph.D.
Principal Investigator
Data Coordinating Center for the NICHD Neonatal Research Network

Rose:

The DSMC wanted the separation data for the SUPPORT SpO2 groups presented in a different manner. Marie has done that analysis, but we haven't sent it out to the group yet. Should we add that to the information we are sharing with the other DSMCs? It is found on the bottom of page 5 in the attached, through the figure on page 6.

Thanks

Abhik

Selected Information from The Fourth Data Safety and Monitoring Committee Report for The SUrfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants (SUPPORT Trial)

CONFIDENTIAL

November 4, 2009

Prepared by the NICHD Neonatal Research Network Data Center at RTI International, Research Triangle Park, NC

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

A. Methods and Procedures

Study Design

The SUrfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants (SUPPORT Trial) is a prospective, randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (NRN). The individual factors to be tested are:

1) A prospective comparison of CPAP and a permissive ventilatory strategy begun in the delivery room and continuing in the NICU with early (≤ 1 hour) surfactant and mechanical ventilation.

2) A prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant no longer requires ventilatory support or oxygen.

The oxygen saturation monitoring portion of the study is designed to allow a blinded comparison of 2 different SpO2 levels using specially designed pulse oximeters that are calibrated to provide actual SpO2 values when the SpO2 is < 85% and > 95%. This methodology provides clinicians and caretakers with the infants' actual SpO2 values during hypoxia and hyperoxia, within the current parameters of clinically accepted practice.

Primary Hypotheses

1) Relative to infants managed with prophylactic/early surfactant and conventional ventilation, the use of early CPAP and a permissive ventilatory strategy in infants of less than 28 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks postmenstrual age (PMA).

2) Relative to infants managed with a higher SpO2 range, the use of a lower SpO2 range (85% to 89%) will result in an increase in survival without the occurrence of threshold ROP and/or the need for surgical intervention.

Secondary Hypotheses

Use of continuous positive airway pressure (CPAP) with a permissive ventilator strategy and/or a lower SpO2 range starting at birth in the delivery room will result in the following:

- A decrease in mortality or neurodevelopmental impairment (NDI) at 18-22 months corrected age
- A decreased frequency of endotracheal intubation before 10 minutes of age
- A decreased incidence of surfactant treatment
- A decreased incidence of air leaks on admission and overall
- A decreased duration of intubation
- A decreased duration of mechanical ventilation
- A decreased duration of oxygen supplementation
- A decreased duration of the percentage of pulse oximetry values > 90%
- A decrease in the percentage of infants who receive postnatal steroids for BPD
- A decreased incidence of BPD at 36 weeks PMA
- A decreased incidence of threshold ROP and/or the need for surgical intervention
- A decreased incidence of necrotizing enterocolitis (NEC)
- A decreased incidence of intraventricular hemorrhage (IVH) and severe IVH
- A decreased incidence of periventricular leukomalacia (PVL)
- A decreased incidence of NDI at 18-22 month follow-up
- A decreased incidence of cerebral palsy at 18-22 month follow-up
- A decreased incidence of blindness of at least one eye at 18-22 month follow-up

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Study Population

Study subjects are infants of 24 0/7 to 27 6/7 weeks gestational age (GA) at birth for which a decision has been made to provide full resuscitation as required. Infants 27 weeks or less gestation (completed weeks by best obstetric estimate) are enrolled because over 80% of such infants in the Network are intubated, usually early in their neonatal course. There are 2 randomization strata, infants of 24 0/7 to 25 6/7 weeks GA, and infants of 26 0/7-27 6/7 weeks GA by best obstetrical estimate. The purpose of stratification is to assure an appropriate distribution of risk among the four study arms. The study is not powered to detect outcome differences between strata.

Inclusion Criteria

- Infants with a minimal gestational age of 24 weeks 0 days to 27 completed weeks (up to 27 6/7ths) by best obstetrical estimate
- Infants who will receive full resuscitation as necessary, i.e., no parental request or physician decision to forego resuscitation
- Infants whose parents/legal guardians have provided consent for enrollment, or
- Infants without known major congenital malformations

Exclusion Criteria

- Any infant transported to the center after delivery
- Infants whose parents/legal guardians refuse consent
- Infants born during a time when the research apparatus/study personnel are not available
- Infants < 24 weeks 0 days or $\geq$ 28 weeks 0 days, completed weeks of gestation

Sampling Recruitment and Screening Procedures

Infants are recruited for this study by approaching parent(s) at the time of hospital admission when there is a perceived risk of premature delivery at 27 6/7ths weeks or less.

Sample Size

The required sample size for this trial was determined to be 1,310 to ensure 80% power for detecting an absolute difference of 10% in the two primary outcomes and the NDI secondary outcome. These results were based on observed prevalence of these outcomes in the Network Generic Data Base (GDB, a registry of all <1500 g births in the Network), and corrected for two primary outcomes (assumed significance level of 2%), for a clustering effect because of multiples being randomized to the same treatment, as well as for attrition. Note that this sample size is not sufficient to permit detection of interaction effects between the two treatments with reasonable power.

Randomization

Randomization is stratified by study site and gestational age group, occurs prior to delivery for consented deliveries, and is performed by utilizing specially prepared double-sealed envelopes. Deliveries are randomized as a unit, thus multiples, twins, triplets etc are randomized to the same arm of the trial. Appropriate sample size adjustments have been made to account for this clustering effect.

Study Intervention

The intervention begins after birth when the infant is given to the resuscitation team. The conduct of the resuscitation follows usual guidelines, and once stabilized, all Control infants in the Ventilation arm receive prophylactic/early surfactant (within 1 hour of age) whereas all

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Treatment infants are placed on CPAP/PEEP following stabilization and intubated only for resuscitation indications.

The assignment to either a high or low SpO2 by study oximeter assignment is performed immediately following NICU admission, with a maximum allowable delay of 2 hours following NICU admission. There are two ranges of SpO2 utilized during this trial. The Low target range is 85% to 89% and the High target range is 91% to 95%. The altered Pulse Oximeters (PO) display a range of 88% to 92% when the SpO2 ranges are in the Target ranges indicated above. Thus a Low range PO reads 88% when the actual SpO2 is approximately 86%, and 92% when the actual SpO2 is 89%. Similarly the High range PO displays 88% when the actual SpO2 is 91% and indicates 92% when the actual SpO2 is approximately 95%.

Interim Monitoring Plan

The Data Safety Monitoring Committee will review the progress of the study with respect to efficacy and adverse events in a sequential fashion using interim monitoring boundaries. Efficacy is measured at approximately 25%, 50%, 75%, and 100% of outcome assessment. Primary outcomes are analyzed at these time points by statistically adjusting for familial clustering and stratification by gestational age stratum and center. To control for the inflation of Type I error associated with sequential testing, O'Brien-Fleming[1] boundaries are calculated using a Lan-DeMets[2] spending function. Safety is monitored at these time points as well using Pocock[3] boundaries for adverse event monitoring.

B. Selected Results

Enrollment

This is an extract from the report prepared for the final planned DSMC look at 100% of the primary outcome data for the SUPPORT Trial. As of February 2009, 1,316 infants have been enrolled in SUPPORT, exceeding the total expected enrollment of 1,310.

Treatment Compliance in Oxygen Saturation Arm

In the oxygen saturation arm, target saturation ranges are 85-89% and 91-95% for the Low and High SpO2 arms, respectively. **Table I** shows the percent of time infants on supplemental oxygen spent in various SpO2 ranges. Supplemental oxygen is defined as FiO2>.21 during the first 14 days of life (FiO2 is reported every two hours) or as documented oxygen use from day of life 15 through 36 weeks (oxygen use is recorded every 6 hours).

Time on supplemental oxygen	Oxygen saturation arm	Percent in narrow target 88-92 (Display)	Percent <84	Percent 84-96	Percent >96
Days of life 1-14	Low SpO2	19.7	11.8	76.2	12.0
	High SpO2	49.3	6.3	79.5	14.2
Day 15 to 36 wks	Low SpO2	15.5	15.4	67.1	17.6
	High SpO2	37.0	10.5	67.7	21.8

Table I Distribution of Time in SpO2 Display Ranges while on Supplemental Oxygen

Separation in Oxygen Saturation Arm **Table II** and **Figure I** address treatment separation in the Oxygen Saturation arm of the SUPPORT Trial. **Table II** shows the amount of time infants in

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

each treatment group spend in room air. Only data from March 2006 to the present are included in Table 3.b, because since that time supplemental oxygen use has been recorded every two hours for day of life (DOL) 1-14 and every 6 hours thereafter. These data indicate some separation between the two treatment groups.

	DOL 1-14		DOL 15+	
	High SpO2	Low SpO2	High SpO2	Low SpO2
Hours in room air (hours in thousands)	35% (57/162)	46% (71/157)	35% (213/600)	46% (254/552)

Table II Percent of Time Spent in Room Air Since March 2006, by Treatment and Day of Life

Figure I shows the distribution of SpO2 values during time spent on supplemental oxygen for infants in the Low and High SpO2 target groups through 36 weeks PMA. There is modest separation between the groups, along with substantial overlap. The area under the overlapping portions of the curves is 85%. Thus, 15% of the area under each curve does not overlap the other.

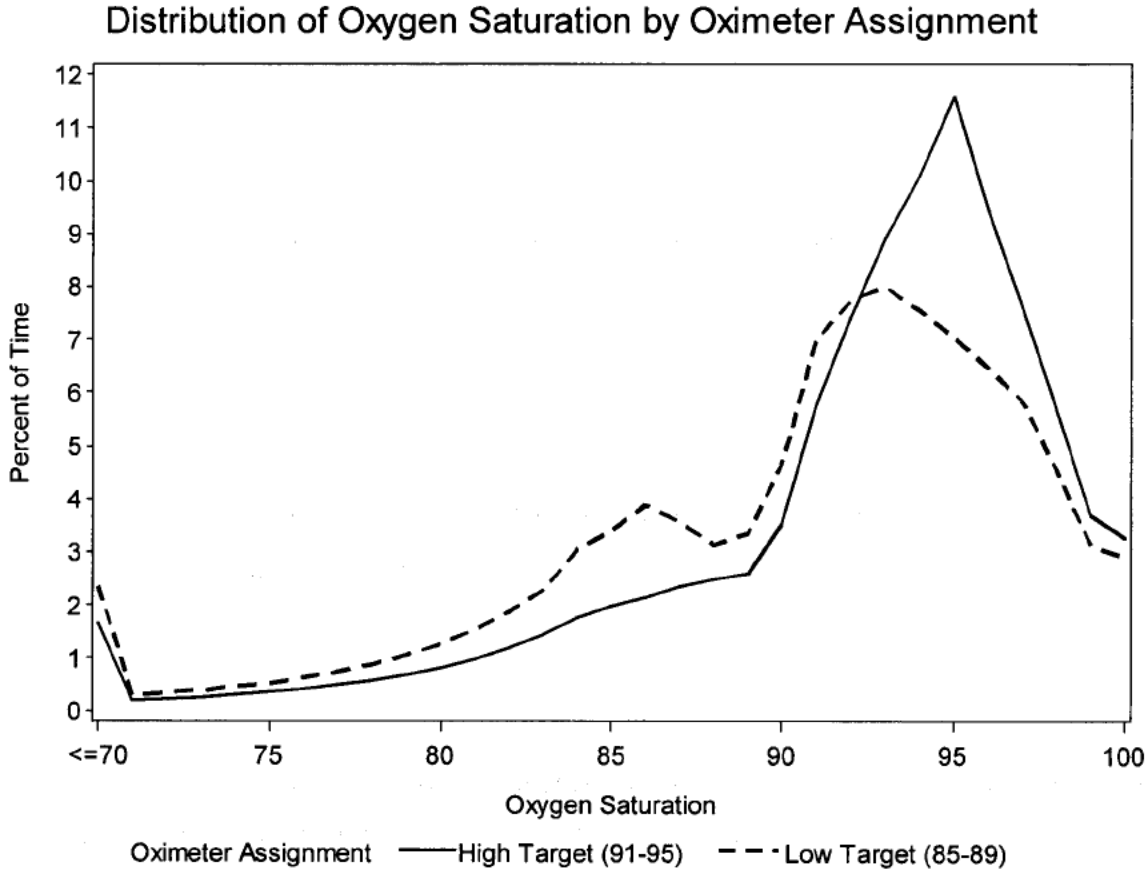

Figure I Percent of Time Spent at Each SpO2 Value for Infants in Low and High Target Groups (Includes only time on supplemental oxygen through 36 weeks PMA)

Upon presentation of the above results to the DSMC, the group requested additional information, which is presented below. Figure II below shows the median SpO2 for each infant,

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

by oxygen saturation target group. A non-parametric Rank Sums test indicates that there is a statistically significant difference between medians of the two distributions ($p<0.0001$). The medians for infants in the low and high target SpO2 groups are 92% and 94%, respectively.

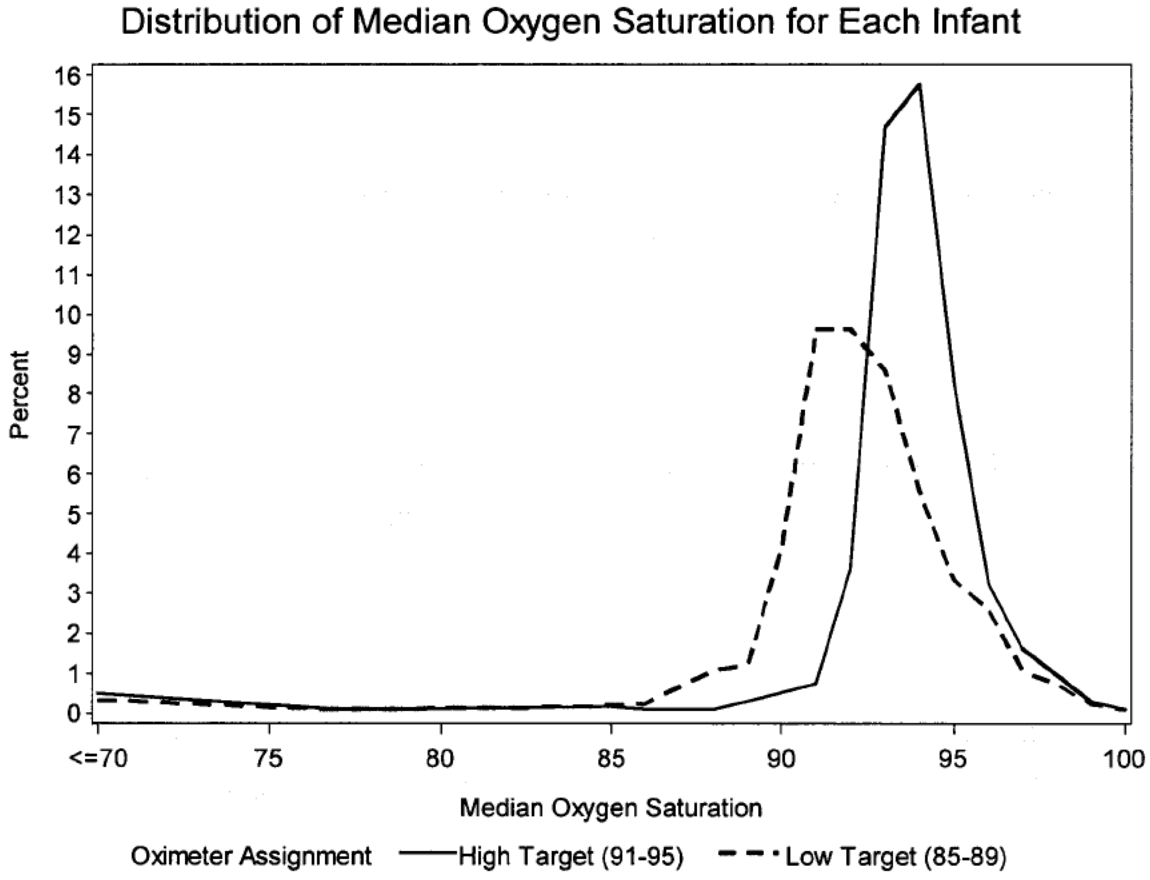

Figure II Infant-Level Median SpO2 Value, by Treatment

Mortality Information

Table III show the percent of infants in each treatment group who died during the course of the SUPPORT Trial. The table also displays adjusted p-values for statistical tests comparing the percent of infants who died in each level of the two treatment factors. The tests are adjusted for familial clustering due to multiple births and for stratification by center and gestational age group. There is a statistically significant difference in the death rate between treatments in the oxygen saturation arm, with higher mortality in the low SpO2 arm.

Outcome	Oxygen Saturation Arm		Adjusted P-value
	Low SpO2 (N=654)	High SpO2 (N=654)	
Death	20% (130/654)	16% (107/662)	0.0412

Table III Death in the Oxygen Saturation Arm

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Gestational age was a significant predictor of death in the tests presented in Table III ($p<0.0001$). **Table IV** presents the mortality information by gestational age stratum. Note that the 26-27 week gestational age stratum includes three infants born at 28 weeks gestational age.

Gestational Age Strata	Oxygen Saturation Arm		Adjusted P-value
	Low SpO2	High SpO2	
GA 24-25 weeks (N=565)	31% (85/276)	25% (73/289)	0.1225
GA 26-27 weeks (N=751)	12% (45/378)	9% (34/373)	0.1811

Table IV Death in the Oxygen Saturation Arm by Gestational Age Group

Cause of Death **Table V** lists causes of death by treatment and gestational age group to address safety concerns regarding RDS and other factors contributing to mortality.

Cause of Death	Low SpO2		High SpO2	
	24-25 wks (N=85)	26-27 wks (N=45)	24-25 wks (N=73)	26-27 wks (N=34)
RDS	27% (23/85)	18% (8/45)	29% (21/73)	29% (10/34)
BPD	9% (8/85)	13% (6/45)	12% (9/73)	3% (1/34)
Infection	19% (16/85)	20% (9/45)	18% (13/73)	24% (8/34)
NEC	20% (17/85)	13% (6/45)	12% (9/73)	15% (5/34)
CNS Insult	12% (10/85)	4% (2/45)	8% (6/73)	9% (3/34)
Immaturity	6% (5/85)	4% (2/45)	4% (3/73)	0% (0/34)
Other	7% (6/85)	27% (12/45)	16% (12/73)	21% (7/34)

Hi Rose,
Personally, I would like to advocate that Ed Donovan and Vivek Narendran both be listed as Cincinnati authors on the CPAP Surfactant manuscript since Ed and Vivek did a lot to move forward the study up front and Vivek was instrumental during the trial. (Ed did a lot with initial start up and education, hosting the training, producing the training video, and was the Cincinnati PI at the beginning of the study). I would like to be listed as the author from Cincinnati on the Oxygen Saturation.
Thanks,
Kurt

Wally,

Here are my edits for the PAS abstract. I am still concerned about just calling the primary outcome threshold ROP or death, as some of our infants who received surgery for ROP did not have a prior exam recorded with threshold ROP. My edits reflect one possible way of rephrasing the outcome.

Thanks,
Marie

Title: Randomized Trial of Oxygen Saturation Targets in Premature Infants.

W.A. Carlo for the SUPPORT Subcommittee of the NICHD Neonatal Research Network.

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, it is important to determine if lower oxygen saturation targets reduce retinopathy without increasing adverse outcomes.

Objective

To test the hypothesis that a lower oxygen saturation target decreases severe ROP (threshold retinopathy of prematurity or need for surgical intervention) or deaths in extremely premature infants.

Methods

~~1316~~ Eligible infants ~~of~~ were $24^{0/7}$ to $27^{6/7}$ weeks gestation inborn at 20 centers of the NICHD Neonatal Research Network. 1316 were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95% using masked oximeters. The primary outcome was a composite of ~~threshold~~ severe ~~retinopathy of prematurity~~ROP ~~and~~/or death.

Comment [MG1]: 3 of the randomized infants were 28 0/7 weeks.

-

Results

~~Threshold~~ Severe ~~retinopathy~~ROP/death did not differ between the oxygen saturation target groups (Table). ~~Threshold~~ Severe ~~retinopathy~~ ROP was decreased (P<0.01~~5~~) in the lower oxygen

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

saturation target group but death was more frequent (P<0.05, Table). Bronchopulmonary dysplasia (BPD) defined as o~~O~~xygen use at 36 weeks decreased in the lower oxygen saturation target group but death or ~~oxygen use~~BPD by the physiologic definition or oxygen use at 36 weeks~~/death~~ did not decrease. Other outcomes did not differ between the groups.

Conclusions

Lower oxygen saturation (85-89%) targets did not significantly decrease the combined outcomes of ~~threshold retinopathy~~severe ROP/death but resulted in an increase in mortality that partially offset a decrease in ~~threshold retinopathy~~severe ROP. The increased mortality is of concern as lower saturation targeting is increasingly being advocated because it has short term retinopathy benefits.

Table:

	Lower Saturation Group n/N (%)	Higher Saturation Group n/N (%)	Adjusted Relative Risk[1] (95% CI)
~~Threshold retinopathy~~Severe ROP/death	171/605 (28.3)	198/616 (32.1)	0.90 (0.76,
Severe ROP~~Threshold retinopathy~~	43/483 (8.9)	95/514 (18.5)	0.51 (0.37,
Death before discharge	130/654 (~~20~~19.9)	107/662 (16.2)	1.27 (1.01, 1.60)

Outcomes of eEmpirical antifungal therapy in extremely low birth weight infants: ~~Effect on mortality and neurodevelopmental outcome~~

[1,2]Rachel G. Greenberg MD, Marie Gantz PhD[3], [1,2]P. Brian Smith MD MHS, [1]C. Michael Cotten MD MHS, Rosemary Higgins MD [1,2]Daniel K. Benjamin Jr MD PhD and the Neonatal Research Network Candida Subcommittee

[1]Department of Pediatrics, Duke University, Durham, NC
[2]Duke University Clinical Research Institute, Durham, NC
[33]RTI International, Research Triangle Park, NC,
[4]National Institute Child Health Human Development Rockville, MD

Background: Invasive candidiasis is a leading cause of infection-related morbidity and mortality in premature infants. Empiric antifungal therapy (EAT) improves outcomes in adults at high risk for fungal infections, but no such studies have been performed in neonates.

Objective: To assess ~~the effect of~~mortality and morbidity ~~timing of empiric antifungal therapy~~outcomes upon receipt of EAT ~~on mortality and morbidity including NDI~~ among extremely low birth weight (ELBW) infants.

Methods: Demographic, clinical, and microbiological data were collected prospectively from infants ≤ 1000 g birth weight cared for at Neonatal Research Network sites. All infants had at least one positive culture for *Candida* from normally sterile body fluid, and had no evidence of congenital candidiasis. The primary outcome variables were survival and time to clearance of *Candida* from all sources. ~~Empirical antifungal therapy~~EAT was defined as receipt of a systemic antifungal on the day before or day on which the first positive culture for *Candida* was drawn (i.e., the day of initial sepsis work-up). ~~We used a logistic regression model for empirical antifungal therapy to determine a propensity score for each infant. The infants were divided into quartiles based on these propensity scores. We created logistic regression models stratified on these quartiles for each of the primary outcome variables using birth weight, age at first positive culture, gender, and presence or absence of empirical antifungal therapy as covariates.~~ Since babies receiving EAT may be systematically different from those who did not, we used propensity score modeling to stratify the analysies according to quartiles of the probability of receiving EAT. ~~Within each quartile, we used~~ Stratified logistic and survival regression ~~for~~models were created for death and days to clearance ~~each of the outcomes~~, with birth weight, age at first positive culture, gender, and presence or absence of EAT as covariates.

Results: 136 infants ~~with~~had invasive candidiasis and clinical data for the week preceding diagnosis were included ~~in the study~~. The median birth weight and gestational age were 680~~3~~ g and 24.9 weeks, respectively; 47 infants (35%) infants died prior to discharge; 39 infants received ~~empiric antifungal therapy~~EAT, and 97 did not. Mortality was comparable among babies who did or did not receive EAT (33% vs 35%). ~~Thirteen of the infants who received empiric antifungal therapy died (33%), and 34 infants who did not receive empiric antifungal therapy (35%) died. The~~For the 96 infants who obtained clearance of infection during the study, median [IQR] time to clearance ~~of infection~~ was 6 [4-14] days. In logistic regression analysis stratified by propensity score quartiles, lower birth weight ($p<0.001$) and male sex ($p=0.03$) were associated with decreased survival. However, ~~presence or absence of empirical antifungal therapy~~EAT was not associated with survival ($p=0.31$); nor was ~~empirical therapy~~it associated with decreased time to clearance of *Candida*.

Conclusions: The use of empiric antifungal therapy in ELBW infants with candidiasis was not associated with increased survival or decreased time to clearance of infection in this cohort of infected infants. The difference in relative benefit observed in older patients compared to these infants may relate to sample size or the non-randomized nature of our study ~~design that did not include randomization~~.

Comment [AD1]: 'Effect' implies causation, and I would avoid using that word.

Comment [MG2]: 137 babies had candida, but only 136 had the clinical data we needed for the analysis. Only 116 had full data and were included in the PS analyses.

Comment [AD3]: This is just among those who received EAT, or in the whole sample?

Subject: Saturation paper

Hi Wally,
Just wondering,
Did you intend to have me listed as a co-author on the saturation paper? I received your note sent to 'all authors'.

At present, I am listed only as the Center PI at Rochester in the Biolerplate.
Rochester's protocol PI for SUPPORT was Nirupama Laroia, so she is appropriately listed as the author from Rochester.

However, I have carried a significant responsibility for the ROP data form, training, instructions, monitoring, etc. for the ROP primary outcome -- I think we could justify adding me to the authors list.

Hi Wally
I am working on the abstract for CPAP and Surf On both Abstracts I would like at least you and me as authors and then whatever follows I will put Finer, Carlo, you can do the flip side I don't know how many authors the NRN requires on abstracts but we will have 2 anyway- if we can do more I would put Wade, Rose and Marie.
Let me know
Neil

Title: The Surfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants –The SUPPORT Trial

Neil N Finer, MD, Waldemar A Carlo, MD and the Neonatal Research Network of the NICHD.
[1]Department of Pediatrics, Division of Neonatology, UCSD School of Medicine and Medical Center, San Diego, Ca, United States and [2]Department of Pediatrics, Division of Neonatology, University of Alabama at Birmingham, Birmingham, Alabama, United States.

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Objective: The SUPPORT Trial was designed to compare early CPAP with early surfactant in ELBW infants.

Design/Methods: ~~The~~ SUPPORT ~~Trial~~study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths ~~weeks~~ to 27 6/7ths weeks. Infants were randomized to either CPAP initiated in the delivery room, and ~~were~~ subsequently treated using a protocol driven limited ventilator strategy, or to. ~~Infants randomized to surfactant, were~~ being intubated and receiving~~ed~~ surfactant within 60 minutes of birth. All infants were also randomized to one of 2 ~~ranges of~~target SpO2 ranges while receiving supplemental oxygen

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was non-significantly reduced at ~~49~~48.7% in the CPAP group versus 54.1% in the surfactant group, (RR 0.91, 95% CI 0.83, 1.01, p=0.07 when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (243.9% vs 32.1%, RR 0.74, 95% CI 0.57, 0.98, p=0.03). Overall, more CPAP infants were alive and off mechanical ventilation by day 7, (55.3% vs 49~~8~~.8%, p=0.01~~1~~) and fewer required intubation (83.1% vs ~~100~~99.7%, P<0.0001) or post natal steroids for BPD (7.2% vs 13.2%, p<~~=~~.0.0005). There was no significant difference in the occurrence of air leaks in the first 14 days, severe intraventricular hemor~~h~~rhage, medical or surgical necrotizing enterocolitis, or patent ductus arteriosus requiring surgery.

Conclusions: Compared with randomization to surfactant within 1 hour of birth, ~~ELBW~~ infants between 24 and 27 6/7ths weeks gestation at birth assigned to treatment with CPAP and a protocol driven limited ventilator strategy have a non significant decreased incidence of death by 36 weeks PMA or BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse

Neil:

Some suggested editorial changes are attached, that cuts down on the words a little bit. I have expressed my reservations about the boldness of the conclusion before; so I won't repeat that again! I can live with it if it is acceptable to the subcommittee and the steering committee.

Thanks

Abhik

Hi Wally
I am working on the abstract for CPAP and Surf On both Abstracts I would like at least you and me as authors and then whatever follows I will put Finer, Carlo, you can do the flip side I don't know how many authors the NRN requires on abstracts but we will have 2 anyway- if we can do more I would put Wade, Rose and Marie.
Let me know
Neil

Title: The Surfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants –The SUPPORT Trial

Neil N Finer, MD, Waldemar A Carlo, MD and the Neonatal Research Network of the NICHD.
[1]Department of Pediatrics, Division of Neonatology, UCSD School of Medicine and Medical Center, San Diego, Ca, United States and [2]Department of Pediatrics, Division of Neonatology, University of Alabama at Birmingham, Birmingham, Alabama, United States.

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Objective: The SUPPORT Trial was designed to compare early CPAP with early surfactant in ELBW infants.

Design/Methods: ~~The~~ SUPPORT ~~Trial~~~~study~~ was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths ~~weeks~~ to 27 6/7ths weeks. Infants were randomized to either CPAP initiated in the delivery room, and ~~were~~ subsequently treated using a protocol driven limited ventilator strategy, or to. ~~Infants randomized to~~ surfactant, ~~were~~ being intubated and receiving~~ed~~ surfactant within 60 minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was non-significantly reduced at 49% in the CPAP group versus 54% in the surfactant group, (RR 0.91, 95% CI 0.83, 1.01, p=0.07 when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03). Overall, more CPAP infants were alive and off mechanical ventilation by day 7, (55% vs 49%, p=0.01~~1~~) and fewer required intubation (83% vs 100%, P<0.0001) or post natal steroids for BPD (7% vs 13%, p<.0.0005). There was no difference in the occurrence of air leaks in the first 14 days, severe intraventricular~~t~~ hemor~~h~~rhage, medical or surgical necrotizing enterocolitis, or patent ductus arteriosus requiring surgery.

Conclusions: Compared with randomization to surfactant within 1 hour of birth, ~~ELBW~~ infants between 24 and 27 6/7ths weeks gestation at birth assigned to treatment with CPAP and a protocol driven limited ventilator strategy have a non significant decreased incidence of death by 36 weeks PMA or BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse

Empirical antifungal therapy in extremely low birth weight (ELBW) infants: Effect on mortality and neurodevelopmental outcome

[1,2]Rachel G. Greenberg MD, Marie Gantz[3], [1,2]P. Brian Smith MD MHS, [1]C. Michael Cotten MD MHS, Rosemary Higgins MD [1,2]Daniel K. Benjamin Jr MD PhD and the Neonatal Research Network Candida Subcommittee

[1]Department of Pediatrics, Duke University, Durham, NC
[2]Duke University Clinical Research Institute, Durham, NC
[33]RTI International, Research Triangle Park, NC,
[4]National Institute Child Health Human Development Rockville, MD

Background: Invasive candidiasis is a leading cause of infection-related morbidity and mortality in premature infants. Empirical antifungal therapy improves outcomes in adults who at high risk for fungal infections, but similar evidence is lacking in neonates~~no such studies have been performed in neonates~~.

Objective: To assess the effect of timing of empirical antifungal therapy on mortality and morbidity including NDI (need to spell out or change the title and include the abbreviation there) among ~~extremely low birth weight~~ (ELBW) infants.

This does not make too much sense to me—"timing" of empiricial therapy? By definition, it is early before the culture results are known –I think that it should be the effect of initiation of empirical antifungal therapy…otherwise, it would just be the timing of antifungal therapy…

Methods: Demographic, clinical, and microbiological data were collected prospectively from infants ≤ 1000 g birth weight cared for at Neonatal Research Network sites. All infants had at least one positive culture for *Candida* from a normally sterile body fluid ~~,~~ and ~~had~~ no evidence of congenital candidiasis. The primary outcome variables were survival and time to clearance of *Candida* from all sources (body fluids or sites?) (but in the title you have neurodev outcome and in objective, NDI??) . Empirical antifungal therapy was defined as receipt of a systemic antifungal agent on the day on which the first positive culture for *Candida* was obtained ~~drawn~~ (i.e., the day of initial sepsis evaluation ~~work-up~~and before culture result known). ~~We used a~~A logistic regression model for empirical antifungal therapy was used to determine a propensity score for each infant. The infants were divided into quartiles based on these propensity scores (should you state something about this??). We created logistic regression models stratified on these quartiles for each of the primary outcome variables (what are these—survival and time to clearance only?) using birth weight, age at first positive culture, gender, and presence or absence of empirical antifungal therapy as covariates. Center? How does it play into this?

Results: 136 infants had invasive (what is this definition? Probably would not state it as such but rather had a positive culture and state the sites—some may have been catheter-associated and would not really call "invasive" if it clears with pulling it and no peripheral one positive --would prefer systemic candidiasis) candidiasis (all blood? How many other sites? Blood, #, CSF #, urine, #) and were included in the study. The median birth weight and gestational age were 683 g and 24.9 weeks, respectively; 47 infants (35%) infants died prior to discharge (related to candida?) ; 39 infants received empirical antifungal therapy, and 97 did not. Thirteen (33%) of the infants who received empirical antifungal therapy died ~~(33%)~~, while ~~and~~ 34 (35%) infants who did not receive empirical antifungal therapy ~~(35%)~~ died. The median [IQR] time to clearance of infection was 6 [4-14] days –did this differ? It's part of your interested outcome. In logistic regression analysis stratified by propensity score quartiles, low birth weight (how is this defined?) ($p<0.001$) and male sex ($p=0.03$) were associated with decreased survival.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

However, presence or absence of empirical antifungal therapy was not associated with survival (p=0.31), nor was empirical therapy associated with decreased time to clearance of *Candida*. From the propensity scoring/logistic regression analysis? you state this before and could just add the p values ....

Your title has neurodevelopmental outcome and you later mention NDI, but there is nothing here on this—need to delete its reference if you did not look at it—or else need to comment on it

Conclusions: The use of empirical antifungal therapy in ELBW infants with systemic candidiasis was not associated with increased survival or decreased time to microbiological clearance of infection in this cohort of infected infants. The difference in relative benefit observed in older patients compared to these infants may relate to sample size or study design that did not include randomization.

Hi Wally,
I attach some small edits aimed at shortening your abstract. I am ok with the abstract as edited... see what I did with the definition of threshold ROP.

I have more comments and thoughts for the manuscript, as I am not as comfortable with that yet. I just wanted to get the PAS abstract to you because I know the deadline is the 9th.

By the way, your letter is addressed to the subcommittee members, but I don't think they are listed on the "To" line. Perhaps you were just sending this out in split mailings.

Dale

Dear SUPPORT Subcommittee members:

Enclosed is a draft of the oxygen saturation paper for your comments. I need everyone's comments before we can submit to the Publications Subcommittee and the whole Steering Committee which gets it at the same time. I am also enclosing the first draft of the PAS abstract which is currently slightly above the word limit.

Title: Randomized Trial of Oxygen Saturation Targets in Premature Infants.

W.A. Carlo for the SUPPORT Subcommittee of the NICHD Neonatal Research Network.

Background

Non randomized studies suggest ~~that~~ the incidence of retinopathy of prematurity(ROP) decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, it is important to determine if lower oxygen saturation targets reduce ROP~~retinopathy~~ without increasing adverse outcomes.

Objective

To test the hypothesis that a lower oxygen saturation target decreases severe ROP~~threshold retinopathy~~ and/or death~~s~~ in extremely premature infants.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95% using masked oximeters. The primary outcome was a composite of Type 1 threshold ROP~~retinopathy of prematurity~~ and/or death.

-

Results

Threshold ROP~~retinopathy~~/death did not differ between the oxygen saturation target groups (Table). Threshold ROP~~retinopathy~~ was decreased ($P<0.05$) in the lower oxygen saturation target group but death was more frequent ($P<0.05$, Table). Oxygen use at 36 weeks decreased in the

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

lower oxygen saturation target group but oxygen use by the physiologic definition ~~or~~ of oxygen use at 36 weeks/death did not decrease. Other outcomes did not differ between the groups.

Conclusions

Lower oxygen saturation (85-89%) targets did not significantly decrease the combined outcomes of threshold ROP~~retinopathy~~/death but ~~resulted in~~ an increase in mortality ~~that~~ partially offset a decrease in threshold ROP ~~retinopathy~~. The increased mortality is of concern as lower saturation targeting is increasingly being advocated because it has short term ROP~~retinopathy~~ benefits.

Table:

	Lower Saturation Group n/N (%)	Higher Saturation Group n/N (%)	Adjusted Relative Risk[1] (95% CI)
Threshold retinopathy/death	170/605 (28)	198/616 (32)	0.90 (0.76, 1.06)
Threshold retinopathy	43/483 (9)	95/514 (18)	0.51 (0.37, 0.71)
Death before discharge	130/654 (20)	107/662 (16)	1.27 (1.01, 1.60)
Bronchopulmonary dysplasia by O_2 use at 36 weeks*	202/540 (37)	265/568 (47)	0.81 (0.71, 0.92)
Bronchopulmonary dysplasia (O_2 use) or death by 36 weeks*	316/654 (48)	359/662 (54)	0.91 (0.82, 1.01)
Bronchopulmonary dysplasia (physiologic) at 36 weeks*	205/540 (38)	237/568 (42)	0.92 (0.81, 1.05)
Intraventricular hemorrhage, grade 3 or 4	83/630 (13)	81/640 (13)	1.06 (0.80, 1.40)
Necrotizing enterocolitis, stage ≥ 2	76/641 (12)	70/649 (11)	1.11 (0.82, 1.51)
Late onset sepsis	228/624 (37)	226/634 (36)	1.03 (0.89, 1.18)
Patent ductus arteriosus	307/641 (48)	324/648 (50)	0.96 (0.86, 1.07)

Thank you for sending the MS and tables Neil,
I have reviewed these, and have some general comments, and have also will forward a track changes version for minor things to address.

Overall, it reads well and is carefully considered. Please consider the following which I feel should be addressed:

1. The CONSORT statement for reporting clinical trials 'requires' a Figure 1 flow sheet that shows what happened to the enrolled infants. (The pulse oximetry paper has one of these that would be more simple for the BPD paper.

2. To either the flow sheet, or to the Table of baseline characteristics, I feel strongly that we have to show the proportion of each group that was randomized to the low sat (or high sat) group, within the two strata would be best. While you are not analyzing an interaction, the reader has to be able to confirm how the randomization worked out in the 2x2 design.

3. It seems very odd (coincidental), that the death rates in the CPAP vs. surfactant groups were identical to the high vs. low sats (16% vs. 20%). Please verify.

4. The small maldistribution of males in the CPAP vs. Surf groups are similar to the maldistribution of males in the high vs. low sats. Again, it seems pertinent to know the distribution in the four cells of the 2x2 table.

I guess I'm getting down to being concerned that the readers/reviewers are going to chafe at having only half a story, and no effort whatsoever to look at any interaction. Just because we don't have the power to detect an interaction does not mean that we are not permitted to look.

Or was the design only for convenience of doing two experiments at one time on the same babies and no a priori thought that there MIGHT be an interaction?

Were the BPD outcomes adjusted for which saturation stratum the infant was in? If you tell me "No, because we stratified randomization for CPAP/surf on the saturation group", then I ask you why did you adjust for center? or gestation?

5. reference #18 is incorrect. This is the design manuscript. Type 1 and Type 2 ROP were not defined until post hoc in writing up the

Hi,
Attached are the two papers in draft form for the SUPPORT Primary outcomes. As noted, there is an increase in death in the lower saturation group (20%) versus the higher saturation group (16%).

This information is confidential and a plan is in place for DSMC communication with ongoing trials of oxygen saturation. If you are contacted by any investigators from other trials or elsewhere, do not share this information. If necessary, refer them to me.

The plan for submission is as follows:

November 16 - 4 PM - call for Steering committee and authors to discuss papers. In the meantime, feel free to send comments to Neil and Wally. The call in number is:
866-675-(b) (6) with passcode (b) (6)

If you are not going to be on the call, send comments in advance or designate someone to serve in your absence.

Immediately following the call, the manuscripts will be finalized for NICHD clearance and for submission to the New England Journal of Medicine.

Thanks in advance to everyone for all their hard work!!!

Title: The Surfactant Positive Airway Pressure and Pulse Oximetry Trial In Extremely Low Birth Weight Infants –The SUPPORT Trial

Neil N Finer, MD, Waldemar A Carlo, MD and the Neonatal Research Network of the NICHD.
[1]Department of Pediatrics, Division of Neonatology, UCSD School of Medicine and Medical Center, San Diego, Ca, United States and [2]Department of Pediatrics, Division of Neonatology, University of Alabama at Birmingham, Birmingham, Alabama, United States.

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Objective: The SUPPORT Trial was designed to compare early CPAP with early surfactant in ELBW infants.

Design/Methods: The SUPPORT Trial~~study~~ was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilator strategy. Infants randomized to surfactant were intubated and received surfactant within 60 minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was non-significantly reduced at 49% in the CPAP group versus 54% in the surfactant group, (RR 0.91, 95% CI 0.83, 1.01, p=0.07 when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03). Overall, more CPAP infants were alive and off mechanical ventilation by day 7, (55% vs 49%, p=0.01~~1~~) and fewer required intubation (83% vs 100%, P<0.0001) or post natal steroids for BPD (7% vs 13%, p<.0.0005). There was no difference in the occurrence of air leaks in the first 14 days, severe intraventricular~~t~~ hemorr~~h~~hage, medical or surgical necrotizing enterocolitis, or patent ductus arteriosus requiring surgery.

Conclusions: Compared with randomization to surfactant within 1 hour of birth, ~~ELBW~~ infants between 24 and 27 6/7ths weeks gestation at birth assigned to treatment with CPAP and a protocol driven limited ventilator strategy have a non significant decreased incidence of death by 36 weeks PMA or BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse

neonatal outcomes. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

Neil,

Here is your paper with updated numbers and my edits, as well as the three source tables I have produced before, now with adjusted p-values and RRs where appropriate.

Will there also be a table showing the primary outcomes? Right now the variables covered in the text and tables don't seem to match completely.

I saw the messages about adding a decimal to the percentages, but not before I had run this version. I will re-run the CPAP and SpO2 paper tables tomorrow with the decimal.

Neil,

Here is your paper with updated numbers and my edits, as well as the three source tables I have produced before, now with adjusted p-values and RRs where appropriate.

Will there also be a table showing the primary outcomes? Right now the variables covered in the text and tables don't seem to match completely.

I saw the messages about adding a decimal to the percentages, but not before I had run this version. I will re-run the CPAP and SpO2 paper tables tomorrow with the decimal.

Acknowledgements (I sent several questions regarding the boilerplate to Stephanie for clarification with Wally's paper)

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Running head: Early CPAP versus Surfactant and outcomes of prematurity

Key words: CPAP, bronchopulmonary dysplasia, extremely low birth weight infant, neonatal mortality, surfactant

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilator strategy. Infants randomized to surfactant were intubated and received surfactant within 60 min minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while ~~in the NICU and~~ receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was 49% in the CPAP group versus 54% in the surfactant group, (RR 0.91, 95% CI 0.83~~2~~, 1.01~~0~~, p=0.07~~6~~ when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.011~~9~~) and fewer required intubation or post natal steroids for BPD, (p<.001).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Conclusions: The use of CPAP in such infants is an effective evidence based alternative to intubation and surfactant.

Introduction:

At the present time, there is no agreement as to the optimal approach to respiratory support for the extremely low birth weight (ELBW) infant following delivery. Positive End Expiratory Pressure (PEEP) has been shown to be of benefit in maintaining functional residual capacity (FRC), and continuous positive airway pressure appears beneficial during cardiopulmonary resuscitation[1]. Gregory et al in 1971 first demonstrated that the use of CPAP started at approximately 5.9 hours (+12.4hrs) for their infants < 1500 gm at birth, improved oxygenation[2] in newborn infants with respiratory distress; these observations were followed by prospective studies that demonstrated improved survival in premature infants treated with early CPAP[3]. A review of prospective studies evaluating early (not delivery room) CPAP in the pre-surfactant, pre-antenatal steroid era found that early CPAP improved survival overall and for infants greater than 1500 gm, and was associated with increased pneumothoraces.[4] A more recent review of prophylactic CPAP started in the delivery room reviewed only 2 available trials and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

found no significant difference between the CPAP and conventionally managed infants and noted a trend to increased adverse outcomes for the CPAP treated infants.[5]

There is substantial retrospective evidence suggesting a benefit for early CPAP for preterm infants with RDS in experiences from both the US and other countries.[678] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following the initiation of early CPAP treatment.[91011]

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[1213] ~~The surfactant trials preceeded widespread use of antenatal corticosteroids to promote lung maturation.~~ Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI).[14] However, the surfactant trials preceded widespread use of antenatal corticosteroids to promote lung maturation and the placebo groups did not received mechanical ventilation which could be injurious.

The recent COIN trial randomized 610 infants from 25 weeks 0 days to 28 weeks 6 days gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[15] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group ~~(9.1~~(9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

with the findings of an earlier meta analysies[44], and a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006~~) with~~) with no statistically significant difference in death or BPD at 36 weeks.

Formatted: Font: 12 pt, Superscript

In view of the current interest in the use of early CPAP and the lack of prospective comparisons of this approach with the evidence based intervention of prophylactic or early surfactant, the SUPPORT Trial~~study~~ was designed to compare these approaches for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design, and the results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324).This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters. (already stated)~~These results will be separately reported~~.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a protocol driven limited ventilator strategy in infants of 24 to 27~~8~~ weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born at a randomizing center without known malformations, for whom a decision had been made to provide full resuscitation, -and parental consent had been obtained. The infants were randomized within each center to 2 gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used at all sites for the delivery room administration of CPAP. CPAP or ventilation with PEEP both at a recommended 5 cm H_2O was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU using the T-piece ~~resuscitator or~~resuscitator or equivalent device and a face mask or nasal prongs. CPAP infants were not to be intubated for surfactant only in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications (need ref) including failure to respond to positive pressure ventilation (PPV) with evidence of continuing cyanosis or bradycardia, the need for chest compressions, the need to administer intratracheal medications, or other situations in which the resuscitation team determined that surfactant is urgently required.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

NICU management: ~~Intubation was allowed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery. While intubation was never required by protocol,~~ CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 ≥ 88% for one hour, an arterial $PaCO_2$ > 65 torr ~~documented on a single blood gas within one hour of intubation~~, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean airway pressure (MAP) < 10 cm H2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations CPAP infants were treated using NICU ~~standardpractice~~standard practice.

Surfactant Arm: All infants were to be intubated within 1 hour of life and receive surfactant, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30 An FiO2 ≤ 35 with a SpO2 ≥88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate ≤ ~~15 bpm~~15 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and ~~be~~ hemodynamically ~~stable with~~stable without

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

~~no~~ evidence of clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms of the trial intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, and thus multiples, were randomized to the same arm of the trial.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, (using the NRN occurrence of death or survival with BPD of 67% using the year 2000 data)~~, and~~, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months (using the NRN occurrence of NDI of 61~~% using~~% using year 2000 data) by 10%. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1312 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the 2 factorial arms.

Comment [MG1]: I believe the SpO2 paper says 1310. They should agree.

In addition there was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which required an attempt at oxygen withdrawal for infants who

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

required < 30% oxygen at 36 weeks and assigned a diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support. [1617]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each gGroup who ~~developed their respective outcome measure of survival~~survived to 36 weeks PMA without BPD~~ at 36 weeks~~. ~~Adjustment was performed as pre-specified for gestational age stratum, center and familial clustering~~ Analysis of this and all other categorical outcomes was performed using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. Continuous outcomes were analyzed using mixed effects linear models. In analysis of all outcomes, adjustment was performed as pre-specified for gestational age stratum, center and familial clustering. A two-sided P value of less than 0.05 was considered statistically significant.

Formatted: Font: 12 pt

An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. {Lan-DeMets spending functions with Pocock or {O'Brien-Fleming} boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and a combination of any of the above events.

Comment [MG2]: Also chest compressions and/or epinephrine in the DR, pulmonary hemorrhage, and nasal breakdown requiring the discontinuation of nasal prongs.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The study was approved by Human Subjects Committees at all participating sites and RTI, the NRN data center that managed and analyzed all the data, and parental consent for participation in the trial was required before delivery

Results:

There were 1316 infants enrolled in this trial from Feb 2005 through ~~to Mar 1~~Feb ~~2009 .~~2009. Enrollment ~~The trial~~ was temporarily suspended by the DSMB because of concerns regarding the oximetry data in November 2005 but after a complete review the trial was continued in February 2006 with no protocol changes. The patient descriptive information for the CPAP versus Surfactant arms is shown in Table 1. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, Apgar scores or race between the 2 treatment groups. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant.

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants, and surfactant was given to 14% of the CPAP versus 51% of the surfactant group; 67% of the CPAP infants received surfactant in the delivery room or NICU, compared to 99% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34% of CPAP infants compared with 93% of surfactant infants, $p<0.001$, Table 2.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post menstrual~~conceptional~~ age was non-significantly reduced for the CPAP group compared with the Surfactant group, 49% versus 54%, (RR 0.91, 05% CI 0.83~~2~~, 1.01~~0~~, p=0.0~~60~~72) when adjusted for gestational age, center and familial clustering as prespecified. Death during the hospitalization was 4% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata,~~,~~ 24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03~~3~~, Table 4. There was a non-significant reduction in the occurrence of BPD using the need for supplemental oxygen, 40% vs 44%, RR 0.9~~4~~3, 95% CI 0.82, 1.06. Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39% vs 41%, RR 0.99, 95% CI 0.87, 1.14), and a non-significant reduction in the occurrence of death or Physiologic BPD at 36 weeks in the CPAP group, (48% vs 51%, RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room, ~~nor any differences in~~ length of stay, ~~or~~ days of oxygen for survivors, or discharge on oxygen~~.~~ (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.01~~9~~). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. Nearly a~~A~~ll infants in the Surfactant arm were intubated, compared with 83% of the CPAP infants who required intubation during their nursery course, (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants, 7% vs 13%, p<0=.00~~1~~05). ~~The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18] was non-~~

~~significantly reduced in in the CPAP compared to the surfactant infants, (23% vs 31%, RR=0.75(0,54, 1.05)~~

Strata Results: 24 – 25 weeks Gestation

There were more non-Hispanic black infants and Hispanic infants in the CPAP group compared with the Surfactant group. The differences are shown in Table 4 (24-25 wk Strata). CPAP infants had a significantly lower mortality while hospitalized 24% vs 32%, RR=0.74, 95% CI 0.57, 0.98, p=0.033. There was a significantly higher exposure to postnatal steroids for BPD, 20% vs 13%, p=0.023 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata. The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[19] or need for surgical intervention for ROP was non-significantly reduced in the CPAP compared to the surfactant infants, (23% vs 31%, RR=0.75, 95% CI 0.54, 1.05).

Comment [MG7]: Race is not in tab le

Comment [MG8]: Not in table

Comment [MG9]: These numbers were reported above but are for the 24-25 week GA stratum

26-27 weeks Gestation

There was no significant difference in mortality for the CPAP vs Surfactant groups, 110% vs 101%. The CPAP infants required fewer days of oxygen, ~~40.6~~44.0 vs ~~47.1~~49.5, p=0.035~~1~~, and lesser days of mechanical ventilation, ~~11.3~~13.7 vs ~~14.9~~16.7, p=0.085~~1~~, and fewer infants received postnatal steroids for BPD, 3% vs 8%, p=<0.008~~1~~.

Comment [MG10]: Non-significant

Discussion:

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The SUPPORT Ttrial is the first prospective randomized multicenter trial to compare early CPAP with early surfactant ~~given within an hour of life~~ in ELBW infants and the only prospective randomized trial comparing CPAP to any other intervention~~other outcome~~ that enrolled infants of 24 weeks gestation. In a preliminary study we found that 100% of infants of 23 weeks gestation required intubation in the DR, and thus decided that such infants would be unlikely to be successfully treated with CPAP alone following delivery.[20] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[21]

Our trial~~study~~ differs from the recently reported COIN trial[15~~15~~] in that we randomized all eligible ELBW infants of consenting families irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven limited ventilator strategy with infants who ~~all~~ were to received surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold approach for intubation and the initiation of mechanical ventilation, and the current practice of a number of NRN units.[6,7] We believed that testing this complete approach would provide a more relevant result as most units currently using early CPAP also tend to have a higher threshold for intubation.

Formatted: Font: 12 pt, Superscript

Our study has demonstrated that intent to treat with early CPAP and protocol driven limited ventilator strategy ~~when compared~~compared to ~~with~~ surfactant given within 1 hour of birth was associated with a non-significant decrease in death ~~or survival with~~by 36 weeks PMA or

BPD as defined by the need for oxygen at 36 weeks from 54% to 49%. We also noted ~~a very~~ significant 8% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.5 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that this lower incidence of death in these infants along ~~with reductions~~with reductions in BPD, ~~ROP, significantly,~~ significantly decreased durations of mechanical ventilation ~~and oxygen~~, a decreased need for intubation and exposure to post natal steroids in the overall CPAP ~~group without~~group without any increase in adverse neonatal ~~outcomes represents~~outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

We prospectively identified a number of safety outcomes that we chose to follow as investigators. These included the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks~~, initially defined as pneumothoraces but later altered to include pulmonary interstitial emphysema, pneumomediastinum and pneumopericardium~~. We did not find an increase in airleaks in the first 14 days of life with the use of early CPAP at 5 cm H2O compared to the use of early surfactant.

The SUPPORT Trial~~study~~ was a factorial design with each infant randomly ~~receiving 2~~receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we did prospectively agree to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of

survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Conclusions:

Compared with ~~the use of~~randomization to surfactant within 1 hour of birth, ELBW infants between 24 and 27 6/7ths weeks gestation at birth assigned to treatment~~ed~~ with CPAP and a protocol driven limited ventilator strategy have a non significant decreased incidence of death ~~or survival with~~by 36 weeks PMA or BPD based on the need for oxygen at 36 weeks ~~PCA~~ PMA with no demonstrable increase in any adverse neonatal outcomes. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

Table 3. BPD outcomes for CPAP vs. Surfactant

Characteristic	CPAP (N=663)	Surfactant (N=653)	Relative Risk for CPAP vs. Surfactant (95% CI)	Adjusted P-value
Death at any time while hospitalized	16% (109/663)	20% (128/653)	0.84 (0.67, 1.05)	0.1259
Death by 36 weeks PMA	14% (94/663)	17% (114/653)	0.81 (0.63, 1.03)	0.0890
BPD (physiologic definition)	39% (223/569)	41% (219/539)	0.99 (0.87, 1.14)	0.9172
BPD (physiologic definition) or death by 36 weeks PMA	48% (317/663)	51% (333/653)	0.95 (0.85, 1.05)	0.3039
BPD (supplemental O2)	40% (229/569)	44% (239/539)	0.94 (0.82, 1.06)	0.3178
BPD (supplemental O2) or death by 36 weeks PMA	49% (323/663)	54% (353/653)	0.91 (0.83, 1.01)	0.0719
ROP	14% (70/517)	14% (68/480)	0.95 (0.7, 1.28)	0.7406
ROP or death	28% (176/620)	32% (193/601)	0.87 (0.74, 1.03)	0.0971

Relative risks are adjusted for GA stratification, center and familial clustering.
Centers with fewer than 10 infants enrolled and those with an incidence of zero for the outcome in question were combined with the geographically closest site for RR calculation.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Table 3 BPD outcomes for CPAP vs. Surfactant
Where GA is 24-25 weeks

Characteristic	CPAP (N=285)	Surfactant (N=280)	Relative Risk for CPAP vs. Surfactant (95% CI)	Adjusted P-value
Death at any time while hospitalized	24% (68/285)	32% (90/280)	0.74 (0.57, 0.98)	0.0335
Death by 36 weeks PMA	20% (57/285)	29% (82/280)	0.68 (0.5, 0.92)	0.0125
BPD (physiologic definition)	55% (125/228)	55% (108/198)	1.06 (0.91, 1.25)	0.4570
BPD (physiologic definition) or death by 36 weeks PMA	64% (182/285)	68% (190/280)	0.96 (0.85, 1.07)	0.4470
BPD (supplemental O2)	54% (122/228)	54% (106/198)	1.05 (0.9, 1.23)	0.5329
BPD (supplemental O2) or death by 36 weeks PMA	63% (179/285)	67% (188/280)	0.95 (0.84, 1.06)	0.3578
ROP	23% (47/202)	31% (55/175)	0.75 (0.54, 1.05)	0.0994
ROP or death	42% (112/266)	55% (144/261)	0.74 (0.62, 0.89)	0.0015

Relative risks are adjusted for GA stratification, center and familial clustering.
Centers with fewer than 10 infants enrolled and those with an incidence of zero for the outcome in question were combined with the geographically closest site for RR calculation.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Table 3. BPD outcomes for CPAP vs. Surfactant
Where GA is 26-27 weeks

Characteristic	CPAP (N=378)	Surfactant (N=373)	Relative Risk for CPAP vs. Surfactant (95% CI)	Adjusted P-value
Death at any time while hospitalized	11% (41/378)	10% (38/373)	1.06 (0.7, 1.6)	0.7966
Death by 36 weeks PMA	10% (37/378)	9% (32/373)	1.12 (0.72, 1.75)	0.6055
BPD (physiologic definition)	29% (98/341)	33% (111/341)	0.92 (0.74, 1.15)	0.4621
BPD (physiologic definition) or death by 36 weeks PMA	36% (135/378)	38% (143/373)	0.94 (0.78, 1.13)	0.4828
BPD (supplemental O2)	31% (107/341)	39% (133/341)	0.84 (0.69, 1.02)	0.0812
BPD (supplemental O2) or death by 36 weeks PMA	38% (144/378)	44% (165/373)	0.87 (0.74, 1.03)	0.1163
ROP	7% (23/315)	4% (13/305)	1.86 (0.94, 3.67)	0.0728
ROP or death	18% (64/354)	14% (49/340)	1.25 (0.88, 1.77)	0.2153

Relative risks are adjusted for GA stratification, center and familial clustering.
Centers with fewer than 10 infants enrolled and those with an incidence of zero for the outcome in question were combined with the geographically closest site for RR calculation.

Table 1. Patient Description for CPAP vs. Surfactant

Variable	Category	CPAP (N=663)	Surfactant (N=653)	Unadjusted P-value
GA (weeks)	24-25	43% (285/663)	43% (280/653)	0.9686
	26-27	57% (378/663)	57% (373/653)	
Male		52% (342/663)	57% (370/653)	0.0646
Race/ethnicity	Non-Hispanic Black	38% (254/663)	36% (235/653)	0.3681
	Non-Hispanic White	38% (250/663)	42% (271/653)	
	Hispanic	21% (138/663)	19% (121/653)	
	Other/unknown	3% (21/663)	4% (26/653)	
Birth weight (grams)	Mean (n=1316)	834.6 ± 188.2	825.5 ± 198.1	0.3962
Gestational age at birth (weeks)	Mean (n=1316)	26.2 ± 1.1	26.2 ± 1.1	0.6463
Antenatal steroids (any)		97% (642/663)	96% (623/652)	0.2248
Antenatal steroids (full course)		74% (486/660)	70% (453/649)	0.1232
Death in the DR (SUPP03/SUPP04)		0% (1/663)	1% (5/653)	0.0978

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Table 1b. DR outcomes for CPAP vs. Surfactant

Characteristic	CPAP (N=663)	Surfactant (N=653)	Relative Risk for CPAP vs. Surfactant (95% CI)	Adjusted P-value
Apgar at 1 minute <3	23% (154/661)	26% (167/653)	0.92 (0.76, 1.11)	0.3835
Apgar at 5 minutes <3	4% (26/663)	5% (32/653)	0.82 (0.5, 1.34)	0.4281

Subject: RE: Oxygen Saturation paper for your comments.
Date: Sunday, November 08, 2009 3:39:30 PM
Attachments: Graphs for Survival Analysis in Oximetry Arm.doc
Oxygen Saturation Target.11.6.09.MASTER_MG.doc

Attached is the Oxygen Saturation paper with my edits and comments. I have updated all numbers and p-values. I have added to the methods section on statistical analysis, and I have added the survival analysis. Instead of using Kaplan-Meier analysis I have used Cox regression in order to adjust for stratification and clustering as in the other analyses. The results were similar, although the difference in the survival curves was significant (p=0.045) after adjustment and non-signficant in the KM analysis without the adjustments. See attached for the two survival curves for comparison.

I will also update all numbers in the CPAP paper and send that out as well.

I think neil and wally on behalf of the support subcommittee of the nichd nrn is fine. If space permits, marie and wade can be added. Limitation in author number was instituted because the authors were taking up to 25 percent of alloted space.
I need the abstract in the next day or so for nichd clearance.
Thanks

Hi Wally
I am working on the abstract for CPAP and Surf
On both Abstracts I would like at least you and me as authors and then whatever follows

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

I will put Finer, Carlo, you can do the flip side
I don't know how many authors the NRN requires on abstracts but we will have 2 anyway- if we can do more I would put Wade, Rose and Marie.
Let me know
Neil

Dear SUPPORT Subcommittee members:

Enclosed is a draft of the oxygen saturation paper for your comments. I need everyone's comments before we can submit to the Publications Subcommittee and the whole Steering Committee which gets it at the same time. I am also enclosing the first draft of the PAS abstract which is currently slightly above the word limit.

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95%. The primary outcome was a composite of threshold retinopathy of prematurity and/or death.

Results

Threshold retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; adjusted p-value = ~~—~~). ~~–~~0.205). Death was more frequent in the lower oxygen saturation target group (20 vs 16%; RR 1.27; CI 1.01, 1.60; adjusted p-value = 0.~~—~~) .041) while threshold retinopathy occurred less often in these infants (9 vs 18%; RR 0.51; CI 0.37, 0.71; adjusted p-value= ~~—~~).0.0001).

Conclusions

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcome of threshold retinopathy/death but resulted in an increase in mortality that partially offset a decrease in threshold retinopathy. The increased mortality is of concern as lower saturation targeting is increasingly

Comment [MG1]: 3 of the randomized infants were actually 28 0/7 weeks GA

Comment [MG2]: Do we need to be specific and say threshold or ROP surgery? Not all infants who had surgery for ROP also had an exam with threshold in our data.

Comment [MG3]: These numbers include 13 infants who died (6 who had ROP and 7 who did not). Do you want me to remove them so it's strictly ROP among survivors?

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

being advocated because of its short term retinopathy benefits (Clinical Trials Gov. Number, NCT 00233324).

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] However, in subsequent years, the practice of restricting oxygen supplementation was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6, 7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy[12], and other morbidities. Although a multicenter study [13] could not determine an association between oxygen levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations of lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3,4,5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery was higher in infants cared for in neonatal intensive care units with maximum target oxygen saturation $\geq$ 92% (3.3 $\pm$ 0.3 versus 1.4 $\pm$ 0.2%) or $\geq$ 98% (5.6 $\pm$ 1.1 versus 3.1 $\pm$ 0.3%).[5] The incidence of severe retinopathy requiring ablation therapy was 27% in units where target saturations were 88 to 98% and only 6% in units where the target was 70 to 90% in a retrospective study comparing outcomes at five neonatal intensive care units.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

to 95% resulted in a substantial reduction in retinopathy.[4, 15, 16] However, actual oxygen saturations achieved were not reported. Furthermore, mortality and neurodevelopmental outcomes were not reported. While data from these recent prospective observational studies, retrospective studies, or controlled but not randomized studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease the incidence of retinopathy of prematurity, there is no conclusive evidence that these oxygenation levels do so without an increase in serious adverse effects, including the possibility of increased risk of death with lower oxygenation as previously reported.

We conducted a 2 x 2 factorial-design multicenter randomized trial of oxygen saturation targeting and protocol-driven limited ventilator strategy. The oxygen saturation part of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of threshold retinopathy of prematurity or death among infants of 24 to 27 weeks gestational age at birth. The ventilation part of this factorial design trial was used to control for the ventilatory approach and test other hypotheses and will be reported separately.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at RTI, the independent data coordinating center, approved the trial. Written informed consent was obtained from the parent or guardian of each participant before delivery.

Patients

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation for which a decision had been made to provide full resuscitation were eligible for enrollment at birth. Outborn infants and those known to have major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of double-sealed opaque envelopes to oxygen saturation targeting of 85 to 89% or 91 to 95% (the lower and higher oxygen saturation target groups, respectively) using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88 to 92% for these oxygen ranges, with an offset of 3% (Massimo Radical Set Pulse Oximeter, Irvine, CA) as previously used to separate oxygen saturations in premature infants.[17] Thus, for example, an oxygen saturation display of 92% would correspond to an actual oxygen saturation of 89% and 95% in the 85-89% and 91-95% target groups, respectively. The oxygen saturation values displayed reverted to actual values when less than ~~85~~84% or higher than ~~95~~96%, the levels of alarm setting recommended in the protocol. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours. Infants weaned to room air but who subsequently received oxygen supplementation before 36 weeks post-menstrual age were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinical, not the research staff. Reports of displayed data by clinical center were provided quarterly for feedback on targeting performance. For the ventilation part of this 2 by 2

Comment [MG4]: The offset was 3% in the target ranges, but at points above and below the target ranges where the display values were transitioning back to "actual" values the offset was not necessarily 3%

Comment [MG5]: A display value of 84 in the high target group corresponds to actual values of 84-87. Below 84 the display values correspond to actual values in both treatment groups.

Comment [MG6]: A display value of 96 in the low target group corresponds to actual values of 93-96. Above 96 the display values correspond to actual values in both treatment groups.

factorial design trial, participants were also randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilation strategy.

Assessments

Research nurses recorded all data using standardized definitions included in the trial Manual of Operations. Data were collected until discharge except for retinopathy. The primary outcome was death before discharge and/or threshold retinopathy or surgery or Avastin treatment for ROP. Threshold retinopathy of prematurity (New Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18]) was coded if any of the following findings were present ~~up to 55 weeks post-menstrual age~~:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic interventions defined as any of the following: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, vitrectomy, and bevacizumab (Avastin).

Other outcomes recorded included only predefined clinical diagnoses and potential adverse events.

Statistical analysis

The primary analysis of categorical outcomes for the oxygen saturation arm of this factorial trial was a generalized estimating equation (GEE) model that used robust Poisson regression to produce adjusted relative risks (RR) comparing incidence rates for infants in each treatment arm who developed the

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

primary outcome. Continuous outcomes were analyzed using mixed effects linear models. Survival analysis using Cox regression produced a hazard ratio (HR) for comparing mortality in the low and high oxygen saturation groups. ~~The model produces relative risk estimates~~ GEE, mixed effect and survival models were adjusted for stratification by center and gestational age as well as for familial clustering due to randomization of multiple births to the same treatment arm. A median actual oxygen saturation value while on oxygen supplementation was determined for each infant to compare the effect of targeting an actual oxygen saturation value between treatment arms.

An absolute difference of 10% between the two treatment groups was considered clinically important. The sample size calculations were based on the rate of death or threshold retinopathy of 50% in the Neonatal Research Network from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or neurodevelopmental impairment at 18-22 months corrected age). Based on an intracluster correlation of 0.12 in this outcome, the sample size was increased by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because this introduced a clustering effect into the design. The required sample size was increased by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the two factorial arms.

Intent-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. A two-sided adjusted p-value of less than 0.05 was considered to be statistically significant. Analyses did not include adjustment for multiple comparisons. An independent Data Safety and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at ~25%, 50%, and 75% of planned enrollment. In addition, the Data Safety and Monitoring Committee, upon request of the investigators, evaluated the oxygen saturation data after enrollment of ~~——~~247 infants to evaluate compliance with the protocol. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of the above events.

Comment [MG7]: Also need for chest compressions and/or epinephrine in the DR, pulmonary hemorrhage, and nasal breakdown requiring the discontinuation of nasal prongs.

RESULTS

1316 infants were enrolled between ~~January~~ February ~~2004~~ 2005 and ~~March~~ February 2009 (Figure 1). Enrollment was temporarily paused after evaluation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and Human Development Director because of concerns regarding compliance with oxygen saturation targets. Separate analysis of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns, and continued enrollment was approved.

The baseline characteristics of the lower saturation group and the higher saturation group were similar (Table 1).

Major outcomes

The primary outcome, threshold retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; ~~p=~~adjusted p-value

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

0.~~____~~-.205; Table 2). Death before discharge occurred in 130 of the 654 (20%) of the infants in the lower oxygen saturation group versus in 107 of the 662 (16%) of the infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; p=0.041). Comparable results were observed for both gestational age strata. ~~Kaplan Meier Analysis indicated~~ Cox regression analysis indicated that there was a significantly higher hazard of death in the lower oxygen saturation group (HR 1.32; CI 1.01, 1.72; p= 0.045) (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Threshold retinopathy or surgical intervention for ROP was decreased in the lower oxygen saturation targeted group (9 vs 18%; RR 0.51; CI 0.37, 0.71; p=0.~~_____~~).-.0001). Oxygen use at 36 weeks PMA was decreased in the lower oxygen saturation group but bronchopulmonary dysplasia determined by the physiological oxygen saturation test at 36 weeks PMA and the composite outcome of bronchopulmonary dysplasia/death by 36 weeks PMA did not differ between the treatment groups. Other pre-specified major outcomes did not differ significantly between the two treatment groups (Table 2).

Comment [MG8]: These numbers include 13 infants who died (6 who had ROP and 7 who did not). Do you want me to remove them so it's strictly ROP among survivors?

The median oxygen saturation of both groups differed substantially but, as expected, there was substantial overlap (Figure 3). These data indicate that actual oxygen saturation levels are slightly higher than targets in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Table 3). Other measures of resource utilization did not differ as well.

DISCUSSION

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The recommended ranges of oxygen saturation targeting for very preterm infants have been determined from non-randomized studies, and restriction of oxygen supplementation is becoming the common practice.[3-5, 19] However, there was an increase in mortality when a restrictive oxygen supplementation was practiced in the 1950s and 1960s. Despite not being based on randomized controlled trials and the limited evidence of safety, lower oxygen saturation targeting has been increasingly adopted by units and physicians in an attempt to decrease retinopathy of prematurity. However, in this large multicenter randomized trial we found that even though lower oxygen saturation targeting reduced threshold retinopathy or the need for surgical intervention for ROP, it also increased the risk for mortality.

This trial was not powered to examine a difference in mortality only between the two oxygen saturation groups. However, this is the largest completed prospective multi-center randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results add to previous data raising the concern that oxygen restriction may increase mortality in very preterm infants. The infants in this trial were more immature than those of any previous trials of oxygen restriction and, thus, may have had a higher susceptibility to the effects of lower oxygen saturation targeting. The previous data on the increased mortality from oxygen restriction were from studies with lower levels of evidence rather than from randomized controlled trials. It is interesting and worrisome that the combined risk difference observed in the trials from the1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.87% mortality increase in the lower targeted SpO2 group that was observed in our trial.

Restriction of oxygenation controlled trials in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17, 20] However, these trials aimed for

saturations of 91 to 94% and 89 to 94% in the lower oxygen saturation group which are closer to the targets of the higher saturation arm in the current trial. The lower target of oxygen saturations or the use of the intervention starting at birth and continuing while oxygen supplementation was needed in the current trial may be related to the adverse outcome.

Recent meta-analyses of trials of restriction of oxygen supplementation based on trials conducted in the 1950s to the 1970s showed a large reduction in severe retinopathy (RR 0.19; CI 0.07, 0.50).[1,21] There have not been other randomized controlled trials of different oxygen targeting starting soon after birth to reduce retinopathy. However, results of most non-randomized studies show that lower oxygen saturation targeting reduces retinopathy of prematurity. The current trial confirmed that lower oxygen targeting results in a large reduction of severe retinopathy.

In summary, lower oxygen saturation targeting did not affect the combined outcome of threshold retinopathy or surgical intervention/death but it increased mortality and decreased threshold retinopathy or surgical intervention. There are several ongoing trials across the world that address the same intervention tested in the current trial as well as a planned prospective meta-analysis.[22] These trials use the same algorithms for oxygen saturation targeting so their data will be easy to combine in a meta-analysis to determine short and long term effects of oxygen saturation targeting. At the present time, it is important that these trials continue and that the investigators and the data safety and monitoring committees of these trials are aware of the results of the current trial so that appropriate decisions can be made regarding their interim analyses, completion of the trials, and dissemination of the data. The current trial raises the concern of adverse hospital outcomes due to oxygen saturation targeting in the 85

Comment [MG9]: Is this still true after some trials have switched to the new oximeter algorithm?

to 89% range. Neurodevelopmental assessments are being performed at 18-22 months corrected age. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years but at the present time, caution should be exercised regarding oxygen targeting in the low range for extremely premature babies, such as those tested in the current trial.

Wally
This manuscript reads very well and appears to be pretty bullet proof. I like Ed Bell's suggestions. I don't see much to comment on except for a few minor points:
1) Abstract/results: if the word allotment allows it would be good to indicate how similar the groups were in demographic characteristics.
2) Results/table 3: No results are listed for alive off mechanical ventilation by day 7.

Abstract: also looks great. Only comment would be in the methods to indicate that the target saturations were for when infants were in oxygen.

Great job!! Tx, AL

Dear SUPPORT Subcommittee members:

Enclosed is a draft of the oxygen saturation paper for your comments. I need everyone's comments before we can submit to the Publications Subcommittee and the whole Steering Committee which gets it at the same time. I am also enclosing the first draft of the PAS abstract which is currently slightly above the word limit.

Title: The Surfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants –The SUPPORT Trial

Neil N Finer, MD, Waldemar A Carlo, MD and the Neonatal Research Network of the NICHD.
[1]Department of Pediatrics, Division of Neonatology, UCSD School of Medicine and Medical Center, San Diego, Ca, United States and [2]Department of Pediatrics, Division of Neonatology, University of Alabama at Birmingham, Birmingham, Alabama, United States.

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Objective: The SUPPORT Trial was designed to compare early CPAP with early surfactant in ELBW infants.

Design/Methods: The SUPPORT Trial~~study~~ was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilator strategy. Infants randomized to surfactant were intubated and received surfactant within 60 minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was non-significantly reduced at 49% in the CPAP group versus 54% in the surfactant group, (RR 0.91, 95% CI 0.83, 1.01, p=0.07 when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03). Overall, more CPAP infants were alive and off mechanical ventilation by day 7, (55% vs 49%, p=0.01~~1~~) and fewer required intubation (83% vs 100%, P<0.0001) or post natal steroids for BPD (7% vs 13%, p<.0.0005). There was no difference in the occurrence of air leaks in the first 14 days, severe intraventricular~~t~~ hemorr~~h~~hage, medical or surgical necrotizing enterocolitis, or patent ductus arteriosus requiring surgery.

Conclusions: Compared with randomization to surfactant within 1 hour of birth, ~~ELBW~~ infants between 24 and 27 6/7ths weeks gestation at birth assigned to treatment with CPAP and a protocol driven limited ventilator strategy have a non significant decreased incidence of death by 36 weeks PMA or BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse

neonatal outcomes. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Title: The Surfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants –The SUPPORT Trial

Neil N Finer, MD, Waldemar A Carlo, MD and the Neonatal Research Network of the NICHD.
[1]Department of Pediatrics, Division of Neonatology, UCSD School of Medicine and Medical Center, San Diego, Ca, United States and [2]Department of Pediatrics, Division of Neonatology, University of Alabama at Birmingham, Birmingham, Alabama, United States.

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Objective: The SUPPORT Trial was designed to compare early CPAP with early surfactant in ELBW infants.

Design/Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilator strategy. Infants randomized to surfactant were intubated and received surfactant within 60 minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while receiving supplemental oxygen

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was non-significantly reduced at 49% in the CPAP group versus 54% in the surfactant group, (RR 0.91, 95% CI 0.83, 1.01, p=0.07 when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03). Overall, more CPAP infants were alive and off mechanical ventilation by day 7, (55% vs 49%, p=0.011) and fewer required intubation (83% vs 100%, P<0.0001) or post natal steroids for BPD (7% vs 13%, p<.0.0005). There was no difference in the occurrence of air leaks in the first 14 days, severe intraventriculat hemorhhage, medical or surgical necrotizing enterocolitis, or patent ductus arteriosus requiring surgery.

Conclusions: Compared with randomization to surfactant within 1 hour of birth, ELBW infants between 24 and 27 6/7ths weeks gestation at birth assigned to treatment with CPAP and a protocol driven limited ventilator strategy have a non significant decreased incidence of death by 36 weeks PMA or BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse neonatal outcomes. Early CPAP is associated with a significant reduction in mortality in the most

immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

Neil,

Here is your paper with updated numbers and my edits, as well as the three source tables I have produced before, now with adjusted p-values and RRs where appropriate.

Will there also be a table showing the primary outcomes? Right now the variables covered in the text and tables don't seem to match completely.

I saw the messages about adding a decimal to the percentages, but not before I had run this version. I will re-run the CPAP and SpO2 paper tables tomorrow with the decimal.

Importance: High

Hello, Wally,

Please find attached your manuscript with some minor edits, mostly in the 1st paragraph on page 11 (introduction). I thought the sentence was too long and convoluted. In addition:

1. While the number of infants enrolled are the same, the dates of enrollment are different in Neil's ("Feb 2005 to Mar 2009") vs. your paper ("January 2004 and March 2009").

2. Besides some missing "p-values" and "numbers" in the text, I thought Table 1 should have p-values.

3. Table 3 is missing data in the last row.

4. I did not get Figure 2. I assume it is OK.

5. Finally, I agree with Ed Bell's comment that the "number needed to prevent threshold ROP" and the "number needed to harm/cause death" should be included in the "discussion" of the mansucript.

Hope this helps.

Best wishes.
Vineet.

Subject: ****CONFIDENTIAL SUPPORT DRAFT MANUSCRIPTS*******

Hi,
Attached are the two papers in draft form for the SUPPORT Primary outcomes. As noted, there is an increase in death in the lower saturation group (20%) versus the higher saturation group (16%).

This information is confidential and a plan is in place for DSMC communication with ongoing trials of oxygen saturation. If you are contacted by any investigators from other trials or elsewhere, do not share this information. If necessary, refer them to me.

The plan for submission is as follows:
November 16 – 4 PM – call for Steering committee and authors to discuss papers. In the meantime, feel free to send comments to Neil and Wally. The call in number is:
866-675(b) (6) with passcode(b) (6)

If you are not going to be on the call, send comments in advance or designate someone to serve in your absence.

Immediately following the call, the manuscripts will be finalized for NICHD clearance and for submission to the New England Journal of Medicine.

Thanks in advance to everyone for all their hard work!!!
Rose

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95%. The primary outcome was a composite of threshold retinopathy of prematurity and/or death.

Results

Threshold retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; p= ___). Death was more frequent in the lower oxygen saturation target group (20 vs 16%; RR 1.27; CI 1.01, 1.60; p= 0.__) while threshold retinopathy occurred less often in these infants (9 vs 18%; RR 0.51; CI 0.37, 0.71; p= ___).

Conclusions

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcome of threshold retinopathy/death but resulted in an increase in mortality that partially offset a decrease in threshold retinopathy. The increased mortality is of concern as lower saturation targeting is increasingly

being advocated because of its short term retinopathy benefits (Clinical Trials Gov. Number, NCT 00233324).

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] However, in subsequent years, the practice of restricting oxygen supplementation was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6, 7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy[12], and other morbidities. Although a multicenter study [13] could not determine an association between oxygen levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations of lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3,4,5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery was higher in infants cared for in neonatal intensive care units with maximum target oxygen saturation $\geq$ 92% (3.3 $\pm$ 0.3 versus 1.4 $\pm$ 0.2%) or $\geq$ 98% (5.6 $\pm$ 1.1 versus 3.1 $\pm$ 0.3%).[5] The incidence of severe retinopathy requiring ablation therapy was 27% in units where target saturations were 88 to 98% and only 6% in units where the target was 70 to 90% in a retrospective study comparing outcomes at five neonatal intensive care units.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

to 95% resulted in a substantial reduction in retinopathy.[4, 15, 16] However, actual oxygen saturations achieved were not reported. Furthermore, mortality and neurodevelopmental outcomes were not reported. While data from these multiple studies suggest that maintenance of oxygenation at lower ranges may decrease the incidence of retinopathy of prematurity, there is no conclusive evidence that these oxygenation levels do so without an increase in serious adverse effects, including death.

We conducted a 2 x 2 factorial-design multicenter randomized trial of oxygen saturation targeting and protocol-driven limited ventilator strategy. The oxygen saturation part of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of threshold retinopathy of prematurity or death among infants of 24 to 27 weeks gestational age at birth. The ventilation part of this factorial design trial was used to control for the ventilatory approach and test other hypotheses and will be reported separately.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at RTI, the independent data coordinating center, approved the trial. Written informed consent was obtained from the parent or guardian of each participant before delivery.

Patients

Infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation for which a decision had been made to provide full resuscitation were eligible for enrollment at birth. Outborn infants and major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of double-sealed opaque envelopes to oxygen saturation targeting of 85 to 89% or 91 to 95% (the lower and higher oxygen saturation target groups, respectively) using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88 to 92% for these oxygen ranges, with an offset of 3% (Massimo Radical Set Pulse Oximeter, Irvine, CA) as previously used to separate oxygen saturations in premature infants.[17] Thus, for example, an oxygen saturation display of 92% would correspond to an actual oxygen saturation of 89% and 95% in the 85-89% and 91-95% target groups, respectively. The oxygen saturation values displayed reverted to actual values when less than 85% or higher than 95%, the levels of alarm setting recommended in the protocol. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours. Infants weaned to room air but who subsequently received oxygen supplementation before 36 weeks post-menstrual age were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinical, not the research staff. Reports of displayed data by clinical center were provided quarterly for feedback on targeting performance. For the ventilation part of this 2 by 2 factorial design trial, participants were also randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilation strategy.

Assessments

Research nurses recorded all data using standardized definitions included in the trial Manual of Operations. Data were collected until discharge except for retinopathy. The primary outcome was death before discharge and/or threshold retinopathy. Threshold retinopathy of prematurity (New Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18]) was coded if any of the following findings were present up to 55 weeks post-menstrual age:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic interventions defined as any of the following: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, vitrectomy, and bevacizumab (Avastin).

Other outcomes recorded included only predefined clinical diagnoses and potential adverse events.

Statistical analysis

The primary analysis for the oxygen saturation arm of this factorial trial was a generalized estimating equation (GEE) model that used robust Poisson regression to produce adjusted relative risks comparing incidence rates for infants in each treatment arm who developed the primary outcome. The model produces relative risk estimates adjusted for stratification by center and gestational age as well as for familial clustering due to randomization of multiple births to the same treatment arm. A median actual oxygen saturation value while on oxygen supplementation was determined for each infant to compare the effect of targeting an actual oxygen saturation value between treatment arms.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

An absolute difference of 10% between the two treatment groups was considered clinically important. The sample size calculations were based on the rate of death or threshold retinopathy of 50% in the Neonatal Research Network from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or neurodevelopmental impairment at 18-22 months corrected age). Based on an intracluster correlation of 0.12 in this outcome, the sample size was increased by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because this introduced a clustering effect into the design. The required sample size was increased by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the two factorial arms.

Intent-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. A two-sided p value of less than 0.05 was considered to be statistically significant. Analyses did not include adjustment for multiple comparisons. An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at ~25%, 50%, and 75% of planned enrollment. In addition, the Data Safety and Monitoring Committee, upon request of the investigators, evaluated the oxygen saturation data after enrollment of ____ infants to evaluate compliance with the protocol. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of the above events.

RESULTS

1316 infants were enrolled between January 2004 and March 2009 (Figure 1). Enrollment was temporarily paused after evaluation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and Human Development Director because of concerns regarding compliance with oxygen saturation targets. Separate analysis of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns, and continued enrollment was approved.

The baseline characteristics of the lower saturation group and the higher saturation group were similar (Table 1).

Major outcomes

The primary outcome, threshold retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; p=0.____; Table 2). Death before discharge occurred in 130 of the 654 (20%) of the infants in the lower oxygen saturation group versus in 107 of the 662 (16%) of the infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; p=0.04). Comparable results were observed for both gestational age strata. Kaplan Meier Analysis indicated _____ (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Threshold retinopathy was decreased in the lower oxygen saturation targeted group (9 vs 18%; RR 0.51; CI 0.37, 0.71; p=0._____). Oxygen use at 36 weeks was decreased in the lower oxygen saturation group but bronchopulmonary

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

dysplasia determined by the physiological oxygen saturation test at 36 weeks and the composite outcome of bronchopulmonary dysplasia/death did not differ between the treatment groups. Other pre-specified major outcomes did not differ significantly between the two treatment groups (Table 2).

The median oxygen saturation of both groups differed substantially but, as expected, there was substantial overlap (Figure 3). These data indicate that actual oxygen saturation levels are slightly higher than targets in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Table 3). Other measures of resource utilization did not differ as well.

DISCUSSION

The recommended ranges of oxygen saturation targeting for very preterm infants have been determined from non-randomized studies, and restriction of oxygen supplementation is becoming the common practice.[3-5, 19] However, there was an increase in mortality when a restrictive oxygen supplementation was practiced in the 1950s and 1960s. Despite not being based on randomized controlled trials and the limited evidence of safety, lower oxygen saturation targeting has been increasingly adopted by units and physicians in an attempt to decrease retinopathy of prematurity. However, in this large multicenter randomized trial we found that even though lower oxygen saturation targeting reduced threshold retinopathy, it also increased the risk for mortality.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

This trial was not powered to examine a difference in mortality only between the two oxygen saturation groups. However, this is the largest completed prospective multi-center randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results add to previous data raising the concern that oxygen restriction may increase mortality in very preterm infants. The infants in this trial were more immature than those of any previous trials of oxygen restriction and, thus, may have had a higher susceptibility to the effects of lower oxygen saturation targeting. The previous data on the increased mortality from oxygen restriction were from studies with lower levels of evidence rather than from randomized controlled trials. It is interesting and worrisome that the combined risk difference observed in the trials from the1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.8% mortality increase in the lower targeted SpO2 group that was observed in our trial.

Restriction of oxygenation controlled trials in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17, 20] However, these trials aimed for saturations of 91 to 94% and 89 to 94% in the lower oxygen saturation group which are closer to the targets of the higher saturation arm in the current trial. The lower target of oxygen saturations or the use of the intervention starting at birth and continuing while oxygen supplementation was needed in the current trial may be related to the adverse outcome.

Recent meta-analyses of trials of restriction of oxygen supplementation based on trials conducted in the 1950s to the 1970s showed a large reduction in severe retinopathy (RR 0.19; CI 0.07, 0.50).[1,21] There have not been other randomized controlled trials of different oxygen targeting starting soon after birth to

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

reduce retinopathy. However, results of most non-randomized studies show that lower oxygen saturation targeting reduces retinopathy of prematurity. The current trial confirmed that lower oxygen targeting results in a large reduction of severe retinopathy.

In summary, lower oxygen saturation targeting did not affect the combined outcome of threshold retinopathy/death but increased mortality and decreased threshold retinopathy. There are several ongoing trials across the world that address the same intervention tested in the current trial as well as a planned prospective meta-analysis.[22] These trials use the same algorithms for oxygen saturation targeting so their data will be easy to combine in a meta-analysis to determine short and long term effects of oxygen saturation targeting. At the present time, it is important that these trials continue and that the investigators and the data safety and monitoring committees of these trials are aware of the results of the current trial so that appropriate decisions can be made regarding their interim analyses, completion of the trials, and dissemination of the data. The current trial raises the concern of adverse hospital outcomes due to oxygen saturation targeting in the 85 to 89% range. Neurodevelopmental assessments are being performed at 18-22 months corrected age. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years but at the present time, caution should be exercised regarding oxygen targeting in the low range for extremely premature babies, such as those tested in the current trial.

Hello, Neil,

The version Rose sent out had the correct author list on the face page. The text was similar in both versions. My (mostly minor) edits are attached for both versions, and the tables. You should be able to pick them up with "track changes".

1. I have highlighted the 2 correct names of the authors on the face page, for your convenience.

2. Please let me know if any questions or clarifications.

Thanks.
Vineet.

Acknowledgements (I sent several questions regarding the boilerplate to Stephanie for clarification with Wally's paper)

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven minimal ventilator strategy. Infants randomized to surfactant were intubated and received surfactant within 60 ~~min~~ minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while in the NICU and receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was 49% in the CPAP group versus 54% in the surfactant group, (RR 0.91, 95% CI 0.82, 1.00, p=0.06 when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.019) and fewer required intubation or post natal steroids for BPD, (p<0.001).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Conclusions: The use of CPAP in such infants is an effective evidence based alternative to intubation and surfactant.

Introduction:

At the present time, there is no agreement as to the optimal approach to respiratory support for the extremely low birth weight (ELBW) infant following delivery. Positive End Expiratory Pressure (PEEP) has been shown to be of benefit in maintaining functional residual capacity (FRC), and continuous positive airway pressure appears beneficial during cardiopulmonary resuscitation[1]. Gregory et al in 1971 first demonstrated that the use of CPAP started at approximately 5.9 hours (+12.4hrs) for their infants < 1500 gm at birth, improved oxygenation[2] in newborn infants with respiratory distress; these observations were followed by prospective studies that demonstrated improved survival in premature infants treated with early CPAP[3]. A review of prospective studies evaluating early (not delivery room) CPAP in the pre-surfactant, pre-antenatal steroid era found that early CPAP improved survival overall and for infants greater than 1500 gm, but~~and~~ was associated with increased pneumothoraces.[4] A more recent review of prophylactic CPAP started in the delivery room reviewed only 2 available trials and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

found no significant difference between the CPAP and conventionally managed infants and noted a trend to increased adverse outcomes for the CPAP treated infants.[5]

There is substantial retrospective evidence suggesting a benefit for early CPAP in experiences from both the US and other countries.[678] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following the initiation of early CPAP treatment.[91011]

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[1213] The surfactant trials preceeded widespread use of antenatal corticosteroids to promote lung maturation. Overall surfactant has not been reported to significantly reduce bronchopulmonary dysplasia (BPD), but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI).[14]

The recent COIN trial randomized 610 infants from 25 weeks 0 days to 28 weeks 6 days gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[15] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (-9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analyses[444], and a reduction in death or the need for oxygen at

28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with no difference in death or BPD at 36 weeks.

In view of the current interest in the use of early CPAP and the lack of prospective comparisons of this approach with the evidence based intervention of prophylactic or early surfactant, the SUPPORT study was designed to compare these approaches for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design, and the results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324).This report describes the prospective comparison of CPAP and a protocol-directed ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters. These results will be separately reported.

The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a protocol driven

minimal ventilator strategy in infants of 24 to 28 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born at a randomizing center without known malformations, for whom a decision had been made to provide full resuscitation, -and parental consent had been obtained. The infants were randomized within each center to 2 gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used at all sites for the delivery room administration of CPAP. CPAP or ventilation with PEEP, both at a recommended 5 cm H_2O, was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU using the T-piece resuscitator- or equivalent device and a face mask or nasal prongs. CPAP infants were not to be intubated for surfactant only in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications (need ref) including failure to respond to positive pressure ventilation (PPV) with evidence of continuing cyanosis or bradycardia, the need for chest compressions, the need to administer intratracheal medications, or other situations in which the resuscitation team determined that surfactant wa~~s~~is urgently required.

NICU management: Intubation was allowed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery. While

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

intubation was never required by protocol, CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 ≥ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within one hour of intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life, infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean airway pressure (MAP) < 10 cm H2O, ventilator rate ≤ 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations, CPAP infants were treated using NICU standard practice.

Surfactant Arm: All infants were to be intubated within 1 hour of life and receive surfactant, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30, ~~An~~ FiO2 ≤ 35 with a SpO2 ≥88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate ≤ 20- bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and be hemodynamically stable with no evidence of clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms of the trial, intubation could be performed at any

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, and thus multiples were randomized to the same arm of the trial.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, (using the NRN occurrence of death or survival with BPD of 67% using the year 2000 data), and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months (using the NRN occurrence of NDI of 61% using year 2000 data) by 10%. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1312 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the 2 factorial arms.

In addition there was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which required an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks and assigned a diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support. [16,17]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

known. The primary analyses focused on the percent of each Group who developed their respective outcome measure of survival without BPD at 36 weeks. Adjustment was performed as pre-specified for gestational age stratum, center and familial clustering using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. A two-sided P value of less than 0.05 was considered statistically significant. An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. (Lan-DeMets spending functions with Pocock and (O'Brien-Fleming) boundaries were used to develop stopping rules for interim safety and efficacy monitoring. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and a combination of any of the above events.

The study was approved by Human Subjects Committees at all participating sites and RTI, the NRN data center that managed and analyzed all the data, and parental consent for participation in the trial was required before delivery

Results:

There were 1316 infants enrolled in this trial from Feb 2005 through to Mar ~~1~~ 2009 . The trial was temporarily suspended by the DSMB because of concerns regarding the oximetry data in November 2005 but after a complete review the trial was continued in February 2006 with no protocol changes. The patient descriptive information for the CPAP versus Surfactant arms is shown in Table 1. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, Apgar scores or

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

race between the 2 treatment groups. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant.

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants, and surfactant was given to 14% of the CPAP versus 51% of the surfactant group; 67% of the CPAP infants received surfactant in the delivery room or NICU, compared to 99% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34% of CPAP infants compared with 93% of surfactant infants, $p<0.001$, Table 2.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post ~~conceptional~~ menstrual age was non-significantly reduced for the CPAP group compared with the Surfactant group, 49% versus 54%, (RR 0.91, 9~~0~~5% CI 0.82, 1.00, p=0.060) when adjusted for gestational age, center and familial clustering as prespecified. Death during the hospitalization was 4% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata~~,~~, 24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03, Table 4. There was a non-significant reduction in the occurrence of BPD using the need for supplemental oxygen, 40% vs 44%, RR 0.93, 95% CI 0.82, 1.06. Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39% vs 41%, RR 0.99, 95% CI 0.87, 1.14), and a non-significant reduction in the occurrence of death or Physiologic BPD at 36 weeks in the CPAP group, (48% vs 51%, RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room nor any differences in length of stay, or days of oxygen for survivors, or discharge on oxygen. (Table 3). More CPAP

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

infants were alive and off mechanical ventilation by day 7, (p=0.019). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All infants in the Surfactant arm were intubated, compared with 83% of the CPAP infants who required intubation during their nursery course, (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants, 7% vs 13%, p=.0005). The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18] was non- significantly reduced in in the CPAP compared to the surfactant infants, (23% vs 31%, RR=0.75 (0.54, 1.05)

Strata Results: 24 – 25 weeks Gestation (post hoc analysis)

There were more non-Hispanic black infants in the CPAP group compared with the Surfactant group. The differences are shown in Table 4 (24-25 wk Strata). CPAP infants had a significantly lower mortality while hospitalized 24% vs 32%, RR=0.74, 95% CI 0.57, 0.98, p=0.03. There was a significantly higher exposure to postnatal steroids for BPD, 20% vs 13%, p=0.02 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata.

26-27 weeks Gestation

There was no difference in mortality for the CPAP vs Surfactant groups, 10% vs 11%. The CPAP infants required fewer days of oxygen, 40.6 vs 47.1, p=0.01, and lesser days of mechanical

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

ventilation, 11.3 vs 14.9, p=0.01, and fewer infants received postnatal steroids for BPD, 3% vs 8%, p<0.01.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare early CPAP with early surfactant given within an hour of life in ELBW infants and the only prospective randomized trial comparing CPAP to any other outcome that enrolled infants of 24 weeks gestation. In a preliminary study we found that 100% of infants of 23 weeks gestation required intubation in the DR, and thus decided that such infants would be unlikely to be successfully treated with CPAP alone following delivery.[19] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[20]

Our study differs from the recently reported COIN trial[15,15,15] in that we randomized all eligible ELBW infants of consenting families irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven minimal ventilator strategy with infants who all received surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven minimal ventilator strategy was a result of previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold approach for intubation and the initiation of mechanical ventilation, and the current practice of a number of NRN units.[6,7] We believed that testing this complete approach would provide a more relevant result as most units currently using early CPAP also tend to have a higher threshold for intubation.

Our study has demonstrated that early CPAP and protocol driven mimimal ventilator strategy when compared with surfactant given within 1 hour of birth was associated with a non-significant decrease in death or survival with BPD as defined by the need for oxygen at 36 weeks from 54% to 49%. We also noted a very significant 8% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.5 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that this lower incidence of death in these infants along with reductions in BPD, ROP, significantly decreased durations of ventilation and oxygen, a decreased need for intubation and exposure to post natal steroids in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

We prospectively identified a number of safety outcomes that we chose to follow as investigators. These included the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks, initially defined as pneumothoraces but later altered to include pulmonary interstitial emphysema, pneumomediastinum and pneumopericardium. We did not find an increase in airleaks with the use of early CPAP at 5 cm H2O compared to the use of early surfactant.

The SUPPORT study was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we did prospectively agree to

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Conclusions:

Compared with the use of surfactant within 1 hour of birth, ELBW infants between 24 and 27 6/7ths weeks gestation at birth treated with CPAP and a protocol driven minimal ventilator strategy have a non significant decreased incidence of death or survival with BPD based on the need for oxygen at 36 weeks PCA with no demonstrable increase in any adverse neonatal outcomes. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilator strategy. Infants randomized to surfactant were intubated and received surfactant within 60 minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while in the NICU and receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was 49% in the CPAP group versus 54% in the surfactant group, (RR 0.91, 95% CI 0.82, 1.00, p=0.06 when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.019) and fewer required intubation or post natal steroids for BPD (p<.001).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Conclusions: The use of CPAP in such infants is an effective evidence based alternative to intubation and surfactant.

Introduction:

At the present time, there is no agreement as to the optimal approach to respiratory support for the extremely low birth weight (ELBW) infant following delivery. Positive End Expiratory Pressure (PEEP) has been shown to be of benefit in maintaining functional residual capacity (FRC), and continuous positive airway pressure appears beneficial during cardiopulmonary resuscitation[1]. Gregory et al in 1971 first demonstrated that the use of CPAP started at approximately 5.9 hours (+12.4hrs) for their infants < 1500 gm at birth, improved oxygenation[2] in newborn infants with respiratory distress; these observations were followed by prospective studies that demonstrated improved survival in premature infants treated with early CPAP[3]. A review of prospective studies evaluating early (not delivery room) CPAP in the pre-surfactant, pre-antenatal steroid era found that early CPAP improved survival overall and for infants greater than 1500 gm, but was associated with increased pneumothoraces.[4] A more recent review of prophylactic CPAP started in the delivery room reviewed only 2 available trials and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

found no significant difference between the CPAP and conventionally managed infants and noted a trend to increased adverse outcomes for the CPAP treated infants.[5]

There is substantial retrospective evidence suggesting a benefit for early CPAP in experiences from both the US and other countries.[678] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following the initiation of early CPAP treatment.[91011]

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[1213] The surfactant trials preceeded widespread use of antenatal corticosteroids to promote lung maturation. Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI). [14]

The recent COIN trial randomized 610 infants from 25 weeks 0 days to 28 weeks 6 days gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[15] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analyses[4], and a reduction in death or the need for oxygen at 28

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with no difference in death or BPD at 36 weeks.

In view of the current interest in the use of early CPAP and the lack of prospective comparisons of this approach with the evidence based intervention of prophylactic or early surfactant, the SUPPORT study was designed to compare these approaches for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design, and the results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324).This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters. These results will be separately reported.

The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a protocol driven limited

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

ventilator strategy in infants of 24 to 28 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born at a randomizing center without known malformations, for whom a decision had been made to provide full resuscitation, and parental consent had been obtained. The infants were randomized within each center to 2 gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used at all sites for the delivery room administration of CPAP. CPAP or ventilation with PEEP, both at a recommended 5 cm H_2O, was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU using the T-piece resuscitator or equivalent device and a face mask or nasal prongs. CPAP infants were not to be intubated for surfactant only in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications (need ref) including failure to respond to positive pressure ventilation (PPV) with evidence of continuing cyanosis or bradycardia, the need for chest compressions, the need to administer intratracheal medications, or other situations in which the resuscitation team determined that surfactant was urgently required.

NICU management: Intubation was allowed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery. While

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

intubation was never required by protocol, CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within one hour of intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life, infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean airway pressure (MAP) < 10 cm H2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations, CPAP infants were treated using NICU standard practice.

Surfactant Arm: All infants were to be intubated within 1 hour of life and receive surfactant, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30, FiO2 $\leq$ 35 with a SpO2 $\geq$88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate $\leq$ 15 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and be hemodynamically stable with no evidence of clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms of the trial, intubation could be performed at any

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, and thus multiples were randomized to the same arm of the trial.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, (using the NRN occurrence of death or survival with BPD of 67% using the year 2000 data), and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months (using the NRN occurrence of NDI of 61% using year 2000 data) by 10%. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1312 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the 2 factorial arms.

In addition there was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which required an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks and assigned a diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support. [16,17]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

known. The primary analyses focused on the percent of each Group who developed their respective outcome measure of survival without BPD at 36 weeks. Adjustment was performed as pre-specified for gestational age stratum, center and familial clustering using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. A two-sided P value of less than 0.05 was considered statistically significant. An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and a combination of any of the above events.

The study was approved by Human Subjects Committees at all participating sites and RTI, the NRN data center that managed and analyzed all the data, and parental consent for participation in the trial was required before delivery

Results:

There were 1316 infants enrolled in this trial from Feb 2005 through to Mar 2009 . The trial was temporarily suspended by the DSMB because of concerns regarding the oximetry data in November 2005 but after a complete review the trial was continued in February 2006 with no protocol changes. The patient descriptive information for the CPAP versus Surfactant arms is shown in Table 1. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, Apgar scores or

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

race between the 2 treatment groups. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant.

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants, and surfactant was given to 14% of the CPAP versus 51% of the surfactant group; 67% of the CPAP infants received surfactant in the delivery room or NICU, compared to 99% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34% of CPAP infants compared with 93% of surfactant infants, $p<0.001$, Table 2.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post conceptional age was non-significantly reduced for the CPAP group compared with the Surfactant group, 49% versus 54%, (RR 0.91, 95% CI 0.82, 1.00, $p=0.060$) when adjusted for gestational age, center and familial clustering as prespecified. Death during the hospitalization was 4% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata, 24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, $p=0.03$, Table 4. There was a non-significant reduction in the occurrence of BPD using the need for supplemental oxygen, 40% vs 44%, RR 0.93, 95% CI 0.82, 1.06. Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39% vs 41%, RR 0.99, 95% CI 0.87, 1.14), and a non-significant reduction in the occurrence of death or Physiologic BPD at 36 weeks in the CPAP group, (48% vs 51%, RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room nor any differences in length of stay, or days of oxygen for survivors, or discharge on oxygen. (Table 3). More CPAP

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

infants were alive and off mechanical ventilation by day 7, (p=0.019). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All infants in the Surfactant arm were intubated, compared with 83% of the CPAP infants who required intubation during their nursery course, (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants, 7% vs 13%, p=.0005). The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18] was non- significantly reduced in in the CPAP compared to the surfactant infants, (23% vs 31%, RR=0.75(0,54, 1.05)

Strata Results: 24 – 25 weeks Gestation

There were more non-Hispanic black infants in the CPAP group compared with the Surfactant group. The differences are shown in Table 4 (24-25 wk Strata). CPAP infants had a significantly lower mortality while hospitalized 24% vs 32%, RR=0.74, 95% CI 0.57, 0.98, p=0.03. There was a significantly higher exposure to postnatal steroids for BPD, 20% vs 13%, p=0.02 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata.

26-27 weeks Gestation

There was no difference in mortality for the CPAP vs Surfactant groups, 10% vs 11%. The CPAP infants required fewer days of oxygen, 40.6 vs 47.1, p=0.01, and lesser days of mechanical

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

ventilation, 11.3 vs 14.9, p=0.01, and fewer infants received postnatal steroids for BPD, 3% vs 8%, p<0.01.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare early CPAP with early surfactant given within an hour of life in ELBW infants and the only prospective randomized trial comparing CPAP to any other outcome that enrolled infants of 24 weeks gestation. In a preliminary study we found that 100% of infants of 23 weeks gestation required intubation in the DR, and thus decided that such infants would be unlikely to be successfully treated with CPAP alone following delivery.[19] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[20]

Our study differs from the recently reported COIN trial[15] in that we randomized all eligible ELBW infants of consenting families irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven limited ventilator strategy with infants who all received surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold approach for intubation and the initiation of mechanical ventilation, and the current practice of a number of NRN units.[6,7] We believed that testing this complete approach would provide a more relevant result as most units currently using early CPAP also tend to have a higher threshold for intubation.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our study has demonstrated that early CPAP and protocol driven limited ventilator strategy when compared with surfactant given within 1 hour of birth was associated with a non-significant decrease in death or survival with BPD as defined by the need for oxygen at 36 weeks from 54% to 49%. We also noted a very significant 8% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.5 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that this lower incidence of death in these infants along with reductions in BPD, ROP, significantly decreased durations of ventilation and oxygen, a decreased need for intubation and exposure to post natal steroids in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

We prospectively identified a number of safety outcomes that we chose to follow as investigators. These included the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks, initially defined as pneumothoraces but later altered to include pulmonary interstitial emphysema, pneumomediastinum and pneumopericardium. We did not find an increase in airleaks with the use of early CPAP at 5 cm H2O compared to the use of early surfactant.

The SUPPORT study was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we did prospectively agree to

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Conclusions:

Compared with the use of surfactant within 1 hour of birth, ELBW infants between 24 and 27 6/7ths weeks gestation at birth treated with CPAP and a protocol driven limited ventilator strategy have a non significant decreased incidence of death or survival with BPD based on the need for oxygen at 36 weeks PCA with no demonstrable increase in any adverse neonatal outcomes. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

Date: Sunday, November 08, 2009 12:58:49 PM

Thanks Abbot
I will fix
The sentence in the paragraph near the end is missing the word overall - Deaths in the lower strata and overall decreases in the other outcomes
As always you can be counted on for a thorough and very useful review. I will incorporate your suggestions
Be well
Neil

Subject: RE: CPAP vs intubation

Neil
Nice paper; you have summarized a tremendous amount of data in very succinct, clear manner. I have a few relatively minor comments:
1) Abstract, last sentence: considering changing the words "such infants" to ELBW infants or state the GA studied
2) Introduction, second paragraph: The first sentence states that BPD is reduced with surfactant but the 3rd sentence states that is is not reduced. A little confusing of the point you are trying to make.
3) Introduction, last paragraph: The statement of the hypothesis would be better placed here rather than in the methods. Especially for casual readers who may only read the abstract/intro/discussion it should be clear what we were testing.
4) Methods/CPAP arm/NICU management: For intubation criteria you have "an arterial PaCO2>65 torr documented on a single blood gas within one hour of intubation". Maybe modify the end of that statement to "...within one hour prior to intubation..."
5) Methods/Surfactant arm: First statement is that all infants were intubated with 1 hours of life and received surfactant. The protocol states that all infants were intubated in the DR and received surfactant in the DR or within one hour of life.
6) Methods/Safety outcomes: Were any DR outcomes monitored and should they be listed.
7) Results/first paragraph: The last sentence deals with DR (epi and deaths) and would be better grouped with the second paragraph. Also why not move death in the DR to table 2 which is focused on DR since table 1 is really demographics.
8) Results/compliance: A reviewer may want some information of compliance with the protocol since in table 2 93% of surfactant infants were intubated in the DR but the protocol states they all should be intubated in the DR.
9) Results/3rd paragraph: The statement "There was a non-significant reduction in the occurrence of BPD using the need for supplemental oxygen..." may be clearer if you state "...occurrence of BPD based on the use of supplemental oxygen..."
10) Severe IVH: do you ever define this? Maybe insert a definition in the table legend.
11) Discussion/3rd paragraph: The statement "We believe that this lower incidence of death in these infants along with reduction in BPD, ROP, significantly decreased durations of ventilation and oxygen...". The only differences that I see are the deaths, off ventilation at day 7 and use of steroids for this strata.
Tx, hope this helps. AL

Subject: Oxygen Saturation paper for your comments.

Dear SUPPORT Subcommittee members:

Enclosed is a draft of the oxygen saturation paper for your comments. I need everyone's comments before we can submit to the Publications Subcommittee and the whole Steering Committee which gets it at the same time. I am also enclosing the first draft of the PAS abstract which is currently slightly above the word limit.

Wally

Subject: RE: ****CONFIDENTIAL SUPPORT DRAFT MANUSCRIPTS*******
Date: Saturday, November 07, 2009 5:35:47 PM

I now have Neal's manuscript and tables
My other E mails are aaf2@case.edu or (b) (6)
University Hospitals has been hit with a major virus and half the computers have been down for a week
They have totally blocked the Internet
all we get is E mail
cannot even use the library
as indicated will try and get the review done rapidly
Results are interesting to say the least
Regards
Av

Hi Rose
I will try
I am heading to Florida on the 11th
By the way I am unable to open the figures and tables - please resend
The ROP/Mortality findings are intriguuing
almost like the 50's when restricted oxygen reduced retinopathy but increased mortality
The follow up will be even more rvealing, especially if the low sat group have more problems - or did the low sats weed out the weak?
Be well
Av
PS Note still burning the candle at both ends

Hi Ed, Av, Jon and David,
You were included on the previous email and I am writing to ask a big favor.

We would like you to consider doing an internal review for these papers and providing me with written comments by 3 PM on 11/16. Let me know if your schedule permits.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

If you are not able to meet the time frame planned, let me know. There is urgency to submission of the papers.

Thanks in advance!!!
Rose

Hi,
Attached are the two papers in draft form for the SUPPORT Primary outcomes. As noted, there is an increase in death in the lower saturation group (20%) versus the higher saturation group (16%).

This information is confidential and a plan is in place for DSMC communication with ongoing trials of oxygen saturation. If you are contacted by any investigators from other trials or elsewhere, do not share this information. If necessary, refer them to me.

The plan for submission is as follows:

November 16 – 4 PM – call for Steering committee and authors to discuss papers. In the meantime, feel free to send comments to Neil and Wally. The call in number is:
866-675(b) (6) with passcode (b) (6)

If you are not going to be on the call, send comments in advance or designate someone to serve in your absence.

Immediately following the call, the manuscripts will be finalized for NICHD clearance and for submission to the New England Journal of Medicine.

Thanks in advance to everyone for all their hard work!!!
Rose

From: Phelps, Dale
To: Gantz, Marie; Wally Carlo, M.D.; Finer, Neil; Higgins, Rosemary (NIH/NICHD) [E]; Das, Abhik; Rich, Wade
Subject: RE: SUPPORT Subcommittee Meeting
Date: Saturday, November 07, 2009 12:25:54 PM

I have some concerns about ROP primary outcomes as late as after 55 weeks. We were pushing things a bit to take it even to 55 weeks. It would depend on the sequence of examination findings.

If an infants lat examination prior to the "determining" examination were at 37 weeks PMA as he was going home, and the next examination was at 58 weeks PMA (over 5 months later), there would not be a way to know what had happened in-between. Could have met criteria, or not.

Let us look carefully at that distribution of PMAs.
We don't want to publish methods/definitions that will not be credible to the ROP community.

Dale

I'll have to look at the distribution of PMAs when final ROP status is obtained.

I will have to change this in the methods.

How late are the ROP outcomes followed?

The ROP outcome is not just up to 55 weeks. Sometimes infants have reached final ROP status after that point.

Not really. Many, if not most, infants were discharged long before 55 weeks PMA. (table 3 shows medians of 99 or 102 days (=~14 weeks). If

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

the infants were median 26 weeks, they were discharged to home at median 40 weeks. No where near 55 weeks.

You have listed ROP in the table of outcomes under the subheading:
"Predischarge Outcome"

That is my issue.

Wally,
The first thing I note is that the ROP is probably reported incorrectly.

To the best of my understanding, the data provided to you by RTI is Threshhold ROP which occurred at any time. Some of these were after discharge.

Dear SUPPORT Subcommittee members:

Enclosed is a draft of the oxygen saturation paper for your comments. I need everyone's comments before we can submit to the Publications Subcommittee and the whole Steering Committee which gets it at the same time. I am also enclosing the first draft of the PAS abstract which is currently slightly above the word limit.

On 11/6/09 1:41 PM, "Higgins, Rosemary (NIH/NICHD) [E]" <higginsr@mail.nih.gov> wrote:

Hi,
Attached are the two papers in draft form for the SUPPORT Primary outcomes. As noted, there is an increase in death in the lower saturation group (20%) versus the higher saturation group (16%).

This information is confidential and a plan is in place for DSMC communication with ongoing trials of oxygen saturation. If you are contacted by any investigators from other trials or elsewhere, do not share this information. If necessary, refer them to me.

The plan for submission is as follows:

November 16 – 4 PM – call for Steering committee and authors to discuss papers. In the meantime, feel free to send comments to Neil and Wally. The call in number is:
866-675-(b) (6) with passcode 5(b) (6)

If you are not going to be on the call, send comments in advance or designate someone to serve in your absence.

Immediately following the call, the manuscripts will be finalized for NICHD clearance and for submission to the New England Journal of Medicine.

Thanks in advance to everyone for all their hard work!!!
Rose

Acknowledgements (I sent several questions regarding the boilerplate to Stephanie for clarification with Wally's paper)

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilator strategy. Infants randomized to surfactant were intubated and received surfactant within 60 min minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while in the NICU and receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was 49% in the CPAP group versus 54% in the surfactant group, (RR 0.91, 95% CI 0.82, 1.00, p=0.06 when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.019) and fewer required intubation or post natal steroids for BPD, (p<.001).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Conclusions: The use of CPAP in such infants is an effective evidence based alternative to intubation and surfactant.

Introduction:

At the present time, there is no agreement as to the optimal approach to respiratory support for the extremely low birth weight (ELBW) infant following delivery. Positive End Expiratory Pressure (PEEP) has been shown to be of benefit in maintaining functional residual capacity (FRC), and continuous positive airway pressure appears beneficial during cardiopulmonary resuscitation[1]. Gregory et al in 1971 first demonstrated that the use of CPAP started at approximately 5.9 hours (+12.4hrs) for their infants < 1500 gm at birth, improved oxygenation[2] in newborn infants with respiratory distress; these observations were followed by prospective studies that demonstrated improved survival in premature infants treated with early CPAP[3]. A review of prospective studies evaluating early (not delivery room) CPAP in the pre-surfactant, pre-antenatal steroid era found that early CPAP improved survival overall and for infants greater than 1500 gm, and was associated with increased pneumothoraces.[4] A more recent review of prophylactic CPAP started in the delivery room reviewed only 2 available trials and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

found no significant difference between the CPAP and conventionally managed infants and noted a trend to increased adverse outcomes for the CPAP treated infants.[5]

There is substantial retrospective evidence suggesting a benefit for early CPAP in experiences from both the US and other countries.[678] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following the initiation of early CPAP treatment.[91011]

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[1213] The surfactant trials preceeded widespread use of antenatal corticosteroids to promote lung maturation. Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI). [14]

The recent COIN trial randomized 610 infants from 25 weeks 0 days to 28 weeks 6 days gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[15] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analyses[4], and a reduction in death or the need for oxygen at 28

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with no difference in death or BPD at 36 weeks.

In view of the current interest in the use of early CPAP and the lack of prospective comparisons of this approach with the evidence based intervention of prophylactic or early surfactant, the SUPPORT study was designed to compare these approaches for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design, and the results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324).This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters. These results will be separately reported.

The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a protocol driven limited

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

ventilator strategy in infants of 24 to 28 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born at a randomizing center without known malformations, for whom a decision had been made to provide full resuscitation, and parental consent had been obtained. The infants were randomized within each center to 2 gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used at all sites for the delivery room administration of CPAP. CPAP or ventilation with PEEP both at a recommended 5 cm H_2O was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU using the T-piece resuscitator or equivalent device and a face mask or nasal prongs. CPAP infants were not to be intubated for surfactant only in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications (need ref) including failure to respond to positive pressure ventilation (PPV) with evidence of continuing cyanosis or bradycardia, the need for chest compressions, the need to administer intratracheal medications, or other situations in which the resuscitation team determined that surfactant is urgently required.

NICU management: Intubation was allowed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery. While

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

intubation was never required by protocol, CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas within one hour of intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean airway pressure (MAP) < 10 cm H2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations CPAP infants were treated using NICU standardpractice.

Surfactant Arm: All infants were to be intubated within 1 hour of life and receive surfactant, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30 An FiO2 ≤ 35 with a SpO2 $\geq$88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate $\leq$ 15 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and be hemodynamically stable with no evidence of clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms of the trial intubation could be performed at any

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, and thus multiples, were randomized to the same arm of the trial.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, (using the NRN occurrence of death or survival with BPD of 67% using the year 2000 data), and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months (using the NRN occurrence of NDI of 61% using year 2000 data) by 10%. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1312 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the 2 factorial arms.

In addition there was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which required an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks and assigned a diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support. [16,17]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

known. The primary analyses focused on the percent of each Group who developed their respective outcome measure of survival without BPD at 36 weeks. Adjustment was performed as pre-specified for gestational age stratum, center and familial clustering using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. A two-sided P value of less than 0.05 was considered statistically significant. An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. (Lan-DeMets spending functions with Pocock (O'Brien-Fleming) boundaries were used to develop stopping rules for interim safety and efficacy monitoring. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and a combination of any of the above events.

The study was approved by Human Subjects Committees at all participating sites and RTI, the NRN data center that managed and analyzed all the data, and parental consent for participation in the trial was required before delivery

Results:

There were 1316 infants enrolled in this trial from Feb 2005 through to Mar 1 2009 . The trial was temporarily suspended by the DSMB because of concerns regarding the oximetry data in November 2005 but after a complete review the trial was continued in February 2006 with no protocol changes. The patient descriptive information for the CPAP versus Surfactant arms is shown in Table 1. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, Apgar scores or

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

race between the 2 treatment groups. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant.

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants, and surfactant was given to 14% of the CPAP versus 51% of the surfactant group; 67% of the CPAP infants received surfactant in the delivery room or NICU, compared to 99% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34% of CPAP infants compared with 93% of surfactant infants, $p<0.001$, Table 2.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post conceptional age was non-significantly reduced for the CPAP group compared with the Surfactant group, 49% versus 54%, (RR 0.91, 05% CI 0.82, 1.00, $p=0.060$) when adjusted for gestational age, center and familial clustering as prespecified. Death during the hospitalization was 4% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata,, 24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, $p=0.03$, Table 4. There was a non-significant reduction in the occurrence of BPD using the need for supplemental oxygen, 40% vs 44%, RR 0.93, 95% CI 0.82, 1.06. Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39% vs 41%, RR 0.99, 95% CI 0.87, 1.14), and a non-significant reduction in the occurrence of death or Physiologic BPD at 36 weeks in the CPAP group, (48% vs 51%, RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room nor any differences in length of stay, or days of oxygen for survivors, or discharge on oxygen. (Table 3). More CPAP

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

infants were alive and off mechanical ventilation by day 7, (p=0.019). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All infants in the Surfactant arm were intubated, compared with 83% of the CPAP infants who required intubation during their nursery course, (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants, 7% vs 13%, p=.0005). The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18] was non- significantly reduced in in the CPAP compared to the surfactant infants, (23% vs 31%, RR=0.75(0,54, 1.05)

Strata Results: 24 – 25 weeks Gestation

There were more non-Hispanic black infants in the CPAP group compared with the Surfactant group. The differences are shown in Table 4 (24-25 wk Strata). CPAP infants had a significantly lower mortality while hospitalized 24% vs 32%, RR=0.74, 95% CI 0.57, 0.98, p=0.03. There was a significantly higher exposure to postnatal steroids for BPD, 20% vs 13%, p=0.02 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata.

26-27 weeks Gestation

There was no difference in mortality for the CPAP vs Surfactant groups, 10% vs 11%. The CPAP infants required fewer days of oxygen, 40.6 vs 47.1, p=0.01, and lesser days of mechanical

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

ventilation, 11.3 vs 14.9, p=0.01, and fewer infants received postnatal steroids for BPD, 3% vs 8%, p<0.01.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare early CPAP with early surfactant given within an hour of life in ELBW infants and the only prospective randomized trial comparing CPAP to any other outcome that enrolled infants of 24 weeks gestation. In a preliminary study we found that 100% of infants of 23 weeks gestation required intubation in the DR, and thus decided that such infants would be unlikely to be successfully treated with CPAP alone following delivery.[19] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[20]

Our study differs from the recently reported COIN trial[15] in that we randomized all eligible ELBW infants of consenting families irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven limited ventilator strategy with infants who all received surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold approach for intubation and the initiation of mechanical ventilation, and the current practice of a number of NRN units.[6,7] We believed that testing this complete approach would provide a more relevant result as most units currently using early CPAP also tend to have a higher threshold for intubation.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our study has demonstrated that early CPAP and protocol driven limited ventilator strategy when compared with surfactant given within 1 hour of birth was associated with a non-significant decrease in death or survival with BPD as defined by the need for oxygen at 36 weeks from 54% to 49%. We also noted a very significant 8% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.5 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that this lower incidence of death in these infants along with reductions in BPD, ROP, significantly decreased durations of ventilation and oxygen, a decreased need for intubation and exposure to post natal steroids in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

We prospectively identified a number of safety outcomes that we chose to follow as investigators. These included the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks, initially defined as pneumothoraces but later altered to include pulmonary interstitial emphysema, pneumomediastinum and pneumopericardium. We did not find an increase in airleaks with the use of early CPAP at 5 cm H2O compared to the use of early surfactant.

The SUPPORT study was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we did prospectively agree to

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Conclusions:

Compared with the use of surfactant within 1 hour of birth, ELBW infants between 24 and 27 6/7ths weeks gestation at birth treated with CPAP and a protocol driven limited ventilator strategy have a non significant decreased incidence of death or survival with BPD based on the need for oxygen at 36 weeks PCA with no demonstrable increase in any adverse neonatal outcomes. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

Hi,

Attached are the two papers in draft form for the SUPPORT Primary outcomes. As noted, there is an increase in death in the lower saturation group (20%) versus the higher saturation group (16%).

This information is confidential and a plan is in place for DSMC

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

communication with ongoing trials of oxygen saturation. If you are contacted by any investigators from other trials or elsewhere, do not share this information. If necessary, refer them to me.

The plan for submission is as follows:

November 16 – 4 PM – call for Steering committee and authors to discuss papers. In the meantime, feel free to send comments to Neil and Wally. The call in number is:
866-675-(b) (6) with passcode (b) (6)

If you are not going to be on the call, send comments in advance or designate someone to serve in your absence.

Immediately following the call, the manuscripts will be finalized for NICHD clearance and for submission to the New England Journal of Medicine.

Thanks in advance to everyone for all their hard work!!!
Rose

Neil:

I am enclosing tracked changes.

I was reading the instructions for authors from NEJM and there are a few issues including the title limit to 75 characters, the recommendation to use the term randomized or something similar in the title or abstract, the word limit of 250 and 2700 for the abstract and text, respectively, the limited use of abbreviations, and trial number at the end of the title.

Great job.

Wally

Attached are the two papers in draft form for the SUPPORT Primary outcomes. As noted, there is an increase in death in the lower saturation group (20%) versus the higher saturation group (16%).

This information is confidential and a plan is in place for DSMC communication with ongoing trials of oxygen saturation. If you are contacted by any investigators from other trials or elsewhere, do not share this information. If necessary, refer them to me.

The plan for submission is as follows:

November 16 – 4 PM – call for Steering committee and authors to discuss papers. In the meantime, feel free to send comments to Neil and Wally. The call in number is:

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven limited ventilator strategy. Infants randomized to surfactant were intubated and received surfactant within 60 min minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while ~~in the NICU and~~ receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was 49% in the CPAP group versus 54% in the surfactant group, (RR 0.91, 95% CI 0.82, 1.00, p=0.06 when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.019) and fewer required intubation or post natal steroids for BPD, (p<.001).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Conclusions: The use of CPAP in such infants is an effective evidence based alternative to intubation and surfactant.

Introduction:

At the present time, there is no agreement as to the optimal approach to respiratory support for the extremely low birth weight (ELBW) infant following delivery. Positive End Expiratory Pressure (PEEP) has been shown to be of benefit in maintaining functional residual capacity (FRC), and continuous positive airway pressure appears beneficial during cardiopulmonary resuscitation[1]. Gregory et al in 1971 first demonstrated that the use of CPAP started at approximately 5.9 hours (+12.4hrs) for their infants < 1500 gm at birth, improved oxygenation[2] in newborn infants with respiratory distress; these observations were followed by prospective studies that demonstrated improved survival in premature infants treated with early CPAP[3]. A review of prospective studies evaluating early (not delivery room) CPAP in the pre-surfactant, pre-antenatal steroid era found that early CPAP improved survival overall and for infants greater than 1500 gm, and was associated with increased pneumothoraces.[4] A more recent review of prophylactic CPAP started in the delivery room reviewed only 2 available trials and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

found no significant difference between the CPAP and conventionally managed infants and noted a trend to increased adverse outcomes for the CPAP treated infants.[5]

There is substantial retrospective evidence suggesting a benefit for early CPAP for preterm infants with RDS in experiences from both the US and other countries.[678] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following the initiation of early CPAP treatment.[91011]

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[1213] ~~The surfactant trials preceeded widespread use of antenatal corticosteroids to promote lung maturation.~~ Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI).[14] However, the surfactant trials preceded widespread use of antenatal corticosteroids to promote lung maturation and the placebo groups did not received mechanical ventilation which could be injurious.

The recent COIN trial randomized 610 infants from 25 weeks 0 days to 28 weeks 6 days gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[15] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group ~~(9.1~~(9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

with the findings of an earlier meta analysies[44], and a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006~~) with~~) with no statistically significant difference in death or BPD at 36 weeks.

Formatted: Font: 12 pt, Superscript

In view of the current interest in the use of early CPAP and the lack of prospective comparisons of this approach with the evidence based intervention of prophylactic or early surfactant, the SUPPORT Trial~~study~~ was designed to compare these approaches for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design, and the results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324).This report describes the prospective comparison of CPAP and a protocol driven limited ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters. (already stated)~~These results will be separately reported~~.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a protocol driven limited ventilator strategy in infants of 24 to 27~~8~~ weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born at a randomizing center without known malformations, for whom a decision had been made to provide full resuscitation, ~~-~~and parental consent had been obtained. The infants were randomized within each center to 2 gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used at all sites for the delivery room administration of CPAP. CPAP or ventilation with PEEP both at a recommended 5 cm H_2O was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU using the T-piece ~~resuscitator or~~resuscitator or equivalent device and a face mask or nasal prongs. CPAP infants were not to be intubated for surfactant only in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications (need ref) including failure to respond to positive pressure ventilation (PPV) with evidence of continuing cyanosis or bradycardia, the need for chest compressions, the need to administer intratracheal medications, or other situations in which the resuscitation team determined that surfactant is urgently required.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

NICU management: ~~Intubation was allowed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery. While intubation was never required by protocol,~~ CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 ≥ 88% for one hour, an arterial $PaCO_2$ > 65 torr ~~documented on a single blood gas within one hour of intubation~~, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean airway pressure (MAP) < 10 cm H2O, ventilator rate < 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations CPAP infants were treated using NICU ~~standardpractice~~standard practice.

Surfactant Arm: All infants were to be intubated within 1 hour of life and receive surfactant, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30 An FiO2 ≤ 35 with a SpO2 ≥88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate ≤ ~~15 bpm~~15 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and ~~be~~ hemodynamically ~~stable with~~stable without

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

~~no~~ evidence of clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms of the trial intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, and thus multiples, were randomized to the same arm of the trial.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, (using the NRN occurrence of death or survival with BPD of 67% using the year 2000 data)~~, and~~, and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months (using the NRN occurrence of NDI of 61~~% using~~% using year 2000 data) by 10%. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1312 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the 2 factorial arms.

In addition there was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which required an attempt at oxygen withdrawal for infants who

required < 30% oxygen at 36 weeks and assigned a diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support. [1617]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each Group who developed their respective outcome measure of survival without BPD at 36 weeks. Adjustment was performed as pre-specified for gestational age stratum, center and familial clustering using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. A two-sided P value of less than 0.05 was considered statistically significant. An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. (Lan-DeMets spending functions with Pocock (O'Brien-Fleming) boundaries were used to develop stopping rules for interim safety and efficacy monitoring. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and a combination of any of the above events.

The study was approved by Human Subjects Committees at all participating sites and RTI, the NRN data center that managed and analyzed all the data, and parental consent for participation in the trial was required before delivery

There were 1316 infants enrolled in this trial from Feb 2005 through to Mar 1 ~~2009 .~~ 2009. Enrollment ~~The trial~~ was temporarily suspended by the DSMB because of concerns regarding the oximetry data in November 2005 but after a complete review the trial was continued in February 2006 with no protocol changes. The patient descriptive information for the CPAP versus Surfactant arms is shown in Table 1. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, Apgar scores or race between the 2 treatment groups. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant.

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants, and surfactant was given to 14% of the CPAP versus 51% of the surfactant group; 67% of the CPAP infants received surfactant in the delivery room or NICU, compared to 99% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34% of CPAP infants compared with 93% of surfactant infants, $p<0.001$, Table 2.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post menstrual~~conceptional~~ age was non-significantly reduced for the CPAP group compared with the Surfactant group, 49% versus 54%, (RR 0.91, 05% CI 0.82, 1.00, p=0.060) when adjusted for gestational age, center and familial clustering as prespecified. Death during the hospitalization was 4% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata,, 24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03, Table 4. There was a non-significant reduction in the occurrence of BPD using the need for supplemental

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

oxygen, 40% vs 44%, RR 0.93, 95% CI 0.82, 1.06. Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39% vs 41%, RR 0.99, 95% CI 0.87, 1.14), and a non-significant reduction in the occurrence of death or Physiologic BPD at 36 weeks in the CPAP group, (48% vs 51%, RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room, ~~nor any differences in~~ length of stay, ~~or~~ days of oxygen for survivors, or discharge on oxygen~~.~~ (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.019). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All infants in the Surfactant arm were intubated, compared with 83% of the CPAP infants who required intubation during their nursery course, (p<0.001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants, 7% vs 13%, p<0=.00105). The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18] was non-significantly reduced in ~~in~~ the CPAP compared to the surfactant infants, (23% vs 31%, RR=0.75(0,54, 1.05)

Strata Results: 24 – 25 weeks Gestation

There were more non-Hispanic black infants in the CPAP group compared with the Surfactant group. The differences are shown in Table 4 (24-25 wk Strata). CPAP infants had a significantly lower mortality while hospitalized 24% vs 32%, RR=0.74, 95% CI 0.57, 0.98, p=0.03. There was a

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

significantly higher exposure to postnatal steroids for BPD, 20% vs 13%, p=0.02 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata.

26-27 weeks Gestation

There was no difference in mortality for the CPAP vs Surfactant groups, 10% vs 11%. The CPAP infants required fewer days of oxygen, 40.6 vs 47.1, p=0.01, and lesser days of mechanical ventilation, 11.3 vs 14.9, p=0.01, and fewer infants received postnatal steroids for BPD, 3% vs 8%, p<0.01.

Discussion:

The SUPPORT Ttrial is the first prospective randomized multicenter trial to compare early CPAP with early surfactant ~~given within an hour of life~~ in ELBW infants and the only prospective randomized trial comparing CPAP to any other intervention~~other outcome~~ that enrolled infants of 24 weeks gestation. In a preliminary study we found that 100% of infants of 23 weeks gestation required intubation in the DR, and thus decided that such infants would be unlikely to be successfully treated with CPAP alone following delivery.[19] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[20]

Our trial~~study~~ differs from the recently reported COIN trial[15~~15~~] in that we randomized all eligible ELBW infants of consenting families irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol

driven limited ventilator strategy with infants who all received surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven limited ventilator strategy was a result of previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold approach for intubation and the initiation of mechanical ventilation, and the current practice of a number of NRN units.[6,7] We believed that testing this complete approach would provide a more relevant result as most units currently using early CPAP also tend to have a higher threshold for intubation.

Our study has demonstrated that early CPAP and protocol driven limited ventilator strategy when compared with surfactant given within 1 hour of birth was associated with a non-significant decrease in death or survival with BPD as defined by the need for oxygen at 36 weeks from 54% to 49%. We also noted a ~~very~~ significant 8% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.5 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that this lower incidence of death in these infants along ~~with reductions~~with reductions in BPD, ROP~~, significantly~~, significantly decreased durations of ventilation and oxygen, a decreased need for intubation and exposure to post natal steroids in the overall CPAP ~~group without~~group without any increase in adverse neonatal ~~outcomes represents~~outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

We prospectively identified a number of safety outcomes that we chose to follow as investigators. These included the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks~~, initially defined as pneumothoraces but later altered to include pulmonary interstitial emphysema, pneumomediastinum and pneumopericardium~~. We did not find an increase in airleaks with the use of early CPAP at 5 cm H2O compared to the use of early surfactant.

The SUPPORT Trial~~study~~ was a factorial design with each infant randomly ~~receiving 2~~receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we did prospectively agree to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Conclusions:

Compared with the use of surfactant within 1 hour of birth, ELBW infants between 24 and 27 6/7ths weeks gestation at birth treated with CPAP and a protocol driven limited ventilator strategy have a non significant decreased incidence of death or survival with BPD based on the need for oxygen at 36 weeks PCA with no demonstrable increase in any adverse neonatal outcomes. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

Running head: Oxygen saturation and outcomes of prematurity

Key words: prematurity, extremely low birth weight infant, neonatal mortality, oxygen toxicity

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95%. The primary outcome was a composite of threshold retinopathy of prematurity and/or death.

Results

Threshold retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; p= ___). Death was more frequent in the lower oxygen saturation target group (20 vs 16%; RR 1.27; CI 1.01, 1.60; p= 0.__) while threshold retinopathy occurred less often in these infants (9 vs 18%; RR 0.51; CI 0.37, 0.71; p= ___).

Conclusions

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcome of threshold retinopathy/death but resulted in an increase in mortality that partially offset a decrease in threshold retinopathy. The increased mortality is of concern as lower saturation targeting is increasingly

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] However, in subsequent years, the practice of restricting oxygen supplementation was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6, 7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy[12], and other morbidities. Although a multicenter study [13] could not determine an association between oxygen levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations of lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3,4,5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery was higher in infants cared for in neonatal intensive care units with maximum target oxygen saturation $\geq$ 92% (3.3 $\pm$ 0.3 versus 1.4 $\pm$ 0.2%) or $\geq$ 98% (5.6 $\pm$ 1.1 versus 3.1 $\pm$ 0.3%).[5] The incidence of severe retinopathy requiring ablation therapy was 27% in units where target saturations were 88 to 98% and only 6% in units where the target was 70 to 90% in a retrospective study comparing outcomes at five neonatal intensive care units.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

to 95% resulted in a substantial reduction in retinopathy.[4, 15, 16] However, actual oxygen saturations achieved were not reported. Furthermore, mortality and neurodevelopmental outcomes were not reported. While data from these recent prospective observational studies, retrospective studies, or controlled but not randomized studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease the incidence of retinopathy of prematurity, there is no conclusive evidence that these oxygenation levels do so without an increase in serious adverse effects, including the possibility of increased risk of death with lower oxygenation as previously reported.

We conducted a 2 x 2 factorial-design multicenter randomized trial of oxygen saturation targeting and protocol-driven limited ventilator strategy. The oxygen saturation part of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of threshold retinopathy of prematurity or death among infants of 24 to 27 weeks gestational age at birth. The ventilation part of this factorial design trial was used to control for the ventilatory approach and test other hypotheses and will be reported separately.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at RTI, the independent data coordinating center, approved the trial. Written informed consent was obtained from the parent or guardian of each participant before delivery.

Patients

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation for which a decision had been made to provide full resuscitation were eligible for enrollment at birth. Outborn infants and major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of double-sealed opaque envelopes to oxygen saturation targeting of 85 to 89% or 91 to 95% (the lower and higher oxygen saturation target groups, respectively) using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88 to 92% for these oxygen ranges, with an offset of 3% (Massimo Radical Set Pulse Oximeter, Irvine, CA) as previously used to separate oxygen saturations in premature infants.[17] Thus, for example, an oxygen saturation display of 92% would correspond to an actual oxygen saturation of 89% and 95% in the 85-89% and 91-95% target groups, respectively. The oxygen saturation values displayed reverted to actual values when less than 85% or higher than 95%, the levels of alarm setting recommended in the protocol. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours. Infants weaned to room air but who subsequently received oxygen supplementation before 36 weeks post-menstrual age were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinical, not the research staff. Reports of displayed data by clinical center were provided quarterly for feedback on targeting performance. For the ventilation part of this 2 by 2

factorial design trial, participants were also randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilation strategy.

Assessments

Research nurses recorded all data using standardized definitions included in the trial Manual of Operations. Data were collected until discharge except for retinopathy. The primary outcome was death before discharge and/or threshold retinopathy. Threshold retinopathy of prematurity (New Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18]) was coded if any of the following findings were present up to 55 weeks post-menstrual age:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic interventions defined as any of the following: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, vitrectomy, and bevacizumab (Avastin).

Other outcomes recorded included only predefined clinical diagnoses and potential adverse events.

Statistical analysis

The primary analysis for the oxygen saturation arm of this factorial trial was a generalized estimating equation (GEE) model that used robust Poisson regression to produce adjusted relative risks comparing incidence rates for infants in each treatment arm who developed the primary outcome. The model produces relative risk estimates adjusted for stratification by center and gestational age as well as for

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

familial clustering due to randomization of multiple births to the same treatment arm. A median actual oxygen saturation value while on oxygen supplementation was determined for each infant to compare the effect of targeting an actual oxygen saturation value between treatment arms.

An absolute difference of 10% between the two treatment groups was considered clinically important. The sample size calculations were based on the rate of death or threshold retinopathy of 50% in the Neonatal Research Network from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or neurodevelopmental impairment at 18-22 months corrected age). Based on an intracluster correlation of 0.12 in this outcome, the sample size was increased by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because this introduced a clustering effect into the design. The required sample size was increased by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the two factorial arms.

Intent-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. A two-sided p value of less than 0.05 was considered to be statistically significant. Analyses did not include adjustment for multiple comparisons. An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at ~25%, 50%, and 75% of planned enrollment. In addition, the Data Safety and Monitoring Committee, upon request of the investigators, evaluated the oxygen saturation data after enrollment of ____ infants to evaluate

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

compliance with the protocol. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of the above events.

RESULTS

1316 infants were enrolled between January 2004 and March 2009 (Figure 1). Enrollment was temporarily paused after evaluation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and Human Development Director because of concerns regarding compliance with oxygen saturation targets. Separate analysis of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns, and continued enrollment was approved.

The baseline characteristics of the lower saturation group and the higher saturation group were similar (Table 1).

Major outcomes

The primary outcome, threshold retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; p=0.____; Table 2). Death before discharge occurred in 130 of the 654 (20%) of the infants in the lower oxygen saturation group versus in 107 of the 662 (16%) of the infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; p=0.04). Comparable results were observed for both gestational age strata. Kaplan Meier Analysis indicated _____ (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Threshold retinopathy was

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

decreased in the lower oxygen saturation targeted group (9 vs 18%; RR 0.51; CI 0.37, 0.71; p=0._____). Oxygen use at 36 weeks was decreased in the lower oxygen saturation group but bronchopulmonary dysplasia determined by the physiological oxygen saturation test at 36 weeks and the composite outcome of bronchopulmonary dysplasia/death did not differ between the treatment groups. Other pre-specified major outcomes did not differ significantly between the two treatment groups (Table 2).

The median oxygen saturation of both groups differed substantially but, as expected, there was substantial overlap (Figure 3). These data indicate that actual oxygen saturation levels are slightly higher than targets in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Table 3). Other measures of resource utilization did not differ as well.

DISCUSSION

The recommended ranges of oxygen saturation targeting for very preterm infants have been determined from non-randomized studies, and restriction of oxygen supplementation is becoming the common practice.[3-5, 19] However, there was an increase in mortality when a restrictive oxygen supplementation was practiced in the 1950s and 1960s. Despite not being based on randomized controlled trials and the limited evidence of safety, lower oxygen saturation targeting has been increasingly adopted by units and physicians in an attempt to decrease retinopathy of prematurity. However, in this large multicenter randomized trial we found that even though lower oxygen saturation targeting reduced threshold retinopathy, it also increased the risk for mortality.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

This trial was not powered to examine a difference in mortality only between the two oxygen saturation groups. However, this is the largest completed prospective multi-center randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results add to previous data raising the concern that oxygen restriction may increase mortality in very preterm infants. The infants in this trial were more immature than those of any previous trials of oxygen restriction and, thus, may have had a higher susceptibility to the effects of lower oxygen saturation targeting. The previous data on the increased mortality from oxygen restriction were from studies with lower levels of evidence rather than from randomized controlled trials. It is interesting and worrisome that the combined risk difference observed in the trials from the1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.8% mortality increase in the lower targeted SpO2 group that was observed in our trial.

Restriction of oxygenation controlled trials in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17, 20] However, these trials aimed for saturations of 91 to 94% and 89 to 94% in the lower oxygen saturation group which are closer to the targets of the higher saturation arm in the current trial. The lower target of oxygen saturations or the use of the intervention starting at birth and continuing while oxygen supplementation was needed in the current trial may be related to the adverse outcome.

Recent meta-analyses of trials of restriction of oxygen supplementation based on trials conducted in the 1950s to the 1970s showed a large reduction in severe retinopathy (RR 0.19; CI 0.07, 0.50).[1,21] There

have not been other randomized controlled trials of different oxygen targeting starting soon after birth to reduce retinopathy. However, results of most non-randomized studies show that lower oxygen saturation targeting reduces retinopathy of prematurity. The current trial confirmed that lower oxygen targeting results in a large reduction of severe retinopathy.

In summary, lower oxygen saturation targeting did not affect the combined outcome of threshold retinopathy/death but increased mortality and decreased threshold retinopathy. There are several ongoing trials across the world that address the same intervention tested in the current trial as well as a planned prospective meta-analysis.[22] These trials use the same algorithms for oxygen saturation targeting so their data will be easy to combine in a meta-analysis to determine short and long term effects of oxygen saturation targeting. At the present time, it is important that these trials continue and that the investigators and the data safety and monitoring committees of these trials are aware of the results of the current trial so that appropriate decisions can be made regarding their interim analyses, completion of the trials, and dissemination of the data. The current trial raises the concern of adverse hospital outcomes due to oxygen saturation targeting in the 85 to 89% range. Neurodevelopmental assessments are being performed at 18-22 months corrected age. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years but at the present time, caution should be exercised regarding oxygen targeting in the low range for extremely premature babies, such as those tested in the current trial.

Subject: ****CONFIDENTIAL SUPPORT DRAFT MANUSCRIPTS*******

Hi,
Attached are the two papers in draft form for the SUPPORT Primary outcomes. As noted, there is an increase in death in the lower saturation group (20%) versus the higher saturation group (16%).

This information is confidential and a plan is in place for DSMC communication with ongoing trials of oxygen saturation. If you are contacted by any investigators from other trials or elsewhere, do not share this information. If necessary, refer them to me.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The plan for submission is as follows:

November 16 – 4 PM – call for Steering committee and authors to discuss papers. In the meantime, feel free to send comments to Neil and Wally. The call in number is:
866-675-(b) (6) with passcode (b) (6)

If you are not going to be on the call, send comments in advance or designate someone to serve in your absence.

Immediately following the call, the manuscripts will be finalized for NICHD clearance and for submission to the New England Journal of Medicine.

Thanks in advance to everyone for all their hard work!!!
Rose

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95%. The primary outcome was a composite of threshold retinopathy of prematurity and/or death.

Results

Threshold retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; p= ___). Death was more frequent in the lower oxygen saturation target group (20 vs 16%; RR 1.27; CI 1.01, 1.60; p= 0.__) while threshold retinopathy occurred less often in these infants (9 vs 18%; RR 0.51; CI 0.37, 0.71; p= ___).

Conclusions

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcome of threshold retinopathy/death but resulted in an increase in mortality that partially offset a decrease in threshold retinopathy. The increased mortality is of concern as lower saturation targeting is increasingly

being advocated because of its short term retinopathy benefits (Clinical Trials Gov. Number, NCT 00233324).

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] However, in subsequent years, the practice of restricting oxygen supplementation was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6, 7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy[12], and other morbidities. Although a multicenter study [13] could not determine an association between oxygen levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations of lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3,4,5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery was higher in infants cared for in neonatal intensive care units with maximum target oxygen saturation $\geq$ 92% (3.3 $\pm$ 0.3 versus 1.4 $\pm$ 0.2%) or $\geq$ 98% (5.6 $\pm$ 1.1 versus 3.1 $\pm$ 0.3%).[5] The incidence of severe retinopathy requiring ablation therapy was 27% in units where target saturations were 88 to 98% and only 6% in units where the target was 70 to 90% in a retrospective study comparing outcomes at five neonatal intensive care units.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

to 95% resulted in a substantial reduction in retinopathy.[4, 15, 16] However, actual oxygen saturations achieved were not reported. Furthermore, mortality and neurodevelopmental outcomes were not reported. While data from these recent prospective observational studies, retrospective studies, or controlled but not randomized studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease the incidence of retinopathy of prematurity, there is no conclusive evidence that these oxygenation levels do so without an increase in serious adverse effects, including the possibility of increased risk of death with lower oxygenation as previously reported.

We conducted a 2 x 2 factorial-design multicenter randomized trial of oxygen saturation targeting and protocol-driven limited ventilator strategy. The oxygen saturation part of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of threshold retinopathy of prematurity or death among infants of 24 to 27 weeks gestational age at birth. The ventilation part of this factorial design trial was used to control for the ventilatory approach and test other hypotheses and will be reported separately.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at RTI, the independent data coordinating center, approved the trial. Written informed consent was obtained from the parent or guardian of each participant before delivery.

Patients

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation for which a decision had been made to provide full resuscitation were eligible for enrollment at birth. Outborn infants and major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of double-sealed opaque envelopes to oxygen saturation targeting of 85 to 89% or 91 to 95% (the lower and higher oxygen saturation target groups, respectively) using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88 to 92% for these oxygen ranges, with an offset of 3% (Massimo Radical Set Pulse Oximeter, Irvine, CA) as previously used to separate oxygen saturations in premature infants.[17] Thus, for example, an oxygen saturation display of 92% would correspond to an actual oxygen saturation of 89% and 95% in the 85-89% and 91-95% target groups, respectively. The oxygen saturation values displayed reverted to actual values when less than 85% or higher than 95%, the levels of alarm setting recommended in the protocol. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours. Infants weaned to room air but who subsequently received oxygen supplementation before 36 weeks post-menstrual age were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinical, not the research staff. Reports of displayed data by clinical center were provided quarterly for feedback on targeting performance. For the ventilation part of this 2 by 2

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

factorial design trial, participants were also randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilation strategy.

Assessments

Research nurses recorded all data using standardized definitions included in the trial Manual of Operations. Data were collected until discharge except for retinopathy. The primary outcome was death before discharge and/or threshold retinopathy. Threshold retinopathy of prematurity (New Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18]) was coded if any of the following findings were present up to 55 weeks post-menstrual age:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic interventions defined as any of the following: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, vitrectomy, and bevacizumab (Avastin).

Other outcomes recorded included only predefined clinical diagnoses and potential adverse events.

Statistical analysis

The primary analysis for the oxygen saturation arm of this factorial trial was a generalized estimating equation (GEE) model that used robust Poisson regression to produce adjusted relative risks comparing incidence rates for infants in each treatment arm who developed the primary outcome. The model produces relative risk estimates adjusted for stratification by center and gestational age as well as for

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

familial clustering due to randomization of multiple births to the same treatment arm. A median actual oxygen saturation value while on oxygen supplementation was determined for each infant to compare the effect of targeting an actual oxygen saturation value between treatment arms.

An absolute difference of 10% between the two treatment groups was considered clinically important. The sample size calculations were based on the rate of death or threshold retinopathy of 50% in the Neonatal Research Network from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or neurodevelopmental impairment at 18-22 months corrected age). Based on an intracluster correlation of 0.12 in this outcome, the sample size was increased by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because this introduced a clustering effect into the design. The required sample size was increased by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the two factorial arms.

Intent-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. A two-sided p value of less than 0.05 was considered to be statistically significant. Analyses did not include adjustment for multiple comparisons. An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at ~25%, 50%, and 75% of planned enrollment. In addition, the Data Safety and Monitoring Committee, upon request of the investigators, evaluated the oxygen saturation data after enrollment of ____ infants to evaluate

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

compliance with the protocol. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of the above events.

RESULTS

1316 infants were enrolled between January 2004 and March 2009 (Figure 1). Enrollment was temporarily paused after evaluation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and Human Development Director because of concerns regarding compliance with oxygen saturation targets. Separate analysis of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns, and continued enrollment was approved.

The baseline characteristics of the lower saturation group and the higher saturation group were similar (Table 1).

Major outcomes

The primary outcome, threshold retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; p=0.____; Table 2). Death before discharge occurred in 130 of the 654 (20%) of the infants in the lower oxygen saturation group versus in 107 of the 662 (16%) of the infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; p=0.04). Comparable results were observed for both gestational age strata. Kaplan Meier Analysis indicated _____ (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Threshold retinopathy was

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

decreased in the lower oxygen saturation targeted group (9 vs 18%; RR 0.51; CI 0.37, 0.71; p=0._____). Oxygen use at 36 weeks was decreased in the lower oxygen saturation group but bronchopulmonary dysplasia determined by the physiological oxygen saturation test at 36 weeks and the composite outcome of bronchopulmonary dysplasia/death did not differ between the treatment groups. Other pre-specified major outcomes did not differ significantly between the two treatment groups (Table 2).

The median oxygen saturation of both groups differed substantially but, as expected, there was substantial overlap (Figure 3). These data indicate that actual oxygen saturation levels are slightly higher than targets in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Table 3). Other measures of resource utilization did not differ as well.

DISCUSSION

The recommended ranges of oxygen saturation targeting for very preterm infants have been determined from non-randomized studies, and restriction of oxygen supplementation is becoming the common practice.[3-5, 19] However, there was an increase in mortality when a restrictive oxygen supplementation was practiced in the 1950s and 1960s. Despite not being based on randomized controlled trials and the limited evidence of safety, lower oxygen saturation targeting has been increasingly adopted by units and physicians in an attempt to decrease retinopathy of prematurity. However, in this large multicenter randomized trial we found that even though lower oxygen saturation targeting reduced threshold retinopathy, it also increased the risk for mortality.

This trial was not powered to examine a difference in mortality only between the two oxygen saturation groups. However, this is the largest completed prospective multi-center randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results add to previous data raising the concern that oxygen restriction may increase mortality in very preterm infants. The infants in this trial were more immature than those of any previous trials of oxygen restriction and, thus, may have had a higher susceptibility to the effects of lower oxygen saturation targeting. The previous data on the increased mortality from oxygen restriction were from studies with lower levels of evidence rather than from randomized controlled trials. It is interesting and worrisome that the combined risk difference observed in the trials from the1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.8% mortality increase in the lower targeted SpO2 group that was observed in our trial.

Restriction of oxygenation controlled trials in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17, 20] However, these trials aimed for saturations of 91 to 94% and 89 to 94% in the lower oxygen saturation group which are closer to the targets of the higher saturation arm in the current trial. The lower target of oxygen saturations or the use of the intervention starting at birth and continuing while oxygen supplementation was needed in the current trial may be related to the adverse outcome.

Recent meta-analyses of trials of restriction of oxygen supplementation based on trials conducted in the 1950s to the 1970s showed a large reduction in severe retinopathy (RR 0.19; CI 0.07, 0.50).[1,21] There

have not been other randomized controlled trials of different oxygen targeting starting soon after birth to reduce retinopathy. However, results of most non-randomized studies show that lower oxygen saturation targeting reduces retinopathy of prematurity. The current trial confirmed that lower oxygen targeting results in a large reduction of severe retinopathy.

In summary, lower oxygen saturation targeting did not affect the combined outcome of threshold retinopathy/death but increased mortality and decreased threshold retinopathy. There are several ongoing trials across the world that address the same intervention tested in the current trial as well as a planned prospective meta-analysis.[22] These trials use the same algorithms for oxygen saturation targeting so their data will be easy to combine in a meta-analysis to determine short and long term effects of oxygen saturation targeting. At the present time, it is important that these trials continue and that the investigators and the data safety and monitoring committees of these trials are aware of the results of the current trial so that appropriate decisions can be made regarding their interim analyses, completion of the trials, and dissemination of the data. The current trial raises the concern of adverse hospital outcomes due to oxygen saturation targeting in the 85 to 89% range. Neurodevelopmental assessments are being performed at 18-22 months corrected age. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years but at the present time, caution should be exercised regarding oxygen targeting in the low range for extremely premature babies, such as those tested in the current trial.

Hi Ed, Av, Jon and David,
You were included on the previous email and I am writing to ask a big favor.

We would like you to consider doing an internal review for these papers and providing me with written comments by 3 PM on 11/16. Let me know if your schedule permits. If you are not able to meet the time frame planned, let me know. There is urgency to submission of the papers.

Thanks in advance!!!
Rose

Subject: ****CONFIDENTIAL SUPPORT DRAFT MANUSCRIPTS*******

Hi,
Attached are the two papers in draft form for the SUPPORT Primary outcomes. As noted, there is an increase in death in the lower saturation group (20%) versus the higher saturation group (16%).

This information is confidential and a plan is in place for DSMC communication with ongoing trials of oxygen saturation. If you are contacted by any investigators from other trials or elsewhere, do not share this information. If necessary, refer them to me.

The plan for submission is as follows:

November 16 – 4 PM – call for Steering committee and authors to discuss papers. In the meantime, feel free to send comments to Neil and Wally. The call in number is:
866-675-(b) (6) with passcode (b) (6)

If you are not going to be on the call, send comments in advance or designate someone to serve in your absence.

Immediately following the call, the manuscripts will be finalized for NICHD clearance and for submission to the New England Journal of Medicine.

Thanks in advance to everyone for all their hard work!!!
Rose

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95%. The primary outcome was a composite of threshold retinopathy of prematurity and/or death.

Results

Threshold retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; p= ___). Death was more frequent in the lower oxygen saturation target group (20 vs 16%; RR 1.27; CI 1.01, 1.60; p= 0.__) while threshold retinopathy occurred less often in these infants (9 vs 18%; RR 0.51; CI 0.37, 0.71; p= ___).

Conclusions

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcome of threshold retinopathy/death but resulted in an increase in mortality that partially offset a decrease in threshold retinopathy. The increased mortality is of concern as lower saturation targeting is increasingly

being advocated because of its short term retinopathy benefits (Clinical Trials Gov. Number, NCT 00233324).

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] However, in subsequent years, the practice of restricting oxygen supplementation was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6, 7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy[12], and other morbidities. Although a multicenter study [13] could not determine an association between oxygen levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations of lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3,4,5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery was higher in infants cared for in neonatal intensive care units with maximum target oxygen saturation $\geq$ 92% (3.3 $\pm$ 0.3 versus 1.4 $\pm$ 0.2%) or $\geq$ 98% (5.6 $\pm$ 1.1 versus 3.1 $\pm$ 0.3%).[5] The incidence of severe retinopathy requiring ablation therapy was 27% in units where target saturations were 88 to 98% and only 6% in units where the target was 70 to 90% in a retrospective study comparing outcomes at five neonatal intensive care units.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

to 95% resulted in a substantial reduction in retinopathy.[4, 15, 16] However, actual oxygen saturations achieved were not reported. Furthermore, mortality and neurodevelopmental outcomes were not reported. While data from these recent prospective observational studies, retrospective studies, or controlled but not randomized studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease the incidence of retinopathy of prematurity, there is no conclusive evidence that these oxygenation levels do so without an increase in serious adverse effects, including the possibility of increased risk of death with lower oxygenation as previously reported.

We conducted a 2 x 2 factorial-design multicenter randomized trial of oxygen saturation targeting and protocol-driven limited ventilator strategy. The oxygen saturation part of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of threshold retinopathy of prematurity or death among infants of 24 to 27 weeks' gestational age at birth. The ventilation part of this factorial design trial was used to control for the ventilatory approach and test other hypotheses and will be reported separately.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at RTI, the independent data coordinating center, approved the trial. Written informed consent was obtained from the parent or guardian of each participant before delivery.

Patients

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation for which a decision had been made to provide full resuscitation were eligible for enrollment at birth. Outborn infants and major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of double-sealed opaque envelopes to oxygen saturation targeting of 85 to 89% or 91 to 95% (the lower and higher oxygen saturation target groups, respectively) using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88 to 92% for these oxygen ranges, with an offset of 3% (Massimo Radical Set Pulse Oximeter, Irvine, CA) as previously used to separate oxygen saturations in premature infants.[17] Thus, for example, an oxygen saturation display of 92% would correspond to an actual oxygen saturation of 89% and 95% in the 85-89% and 91-95% target groups, respectively. The oxygen saturation values displayed reverted to actual values when less than 85% or higher than 95%, the levels of alarm setting recommended in the protocol. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours. Infants weaned to room air but who subsequently received oxygen supplementation before 36 weeks post-menstrual age were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinical, not the research staff. Reports of displayed data by clinical center were provided quarterly for feedback on targeting performance. For the ventilation part of this 2 by 2

factorial design trial, participants were also randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilation strategy.

Assessments

Research nurses recorded all data using standardized definitions included in the trial Manual of Operations. Data were collected until discharge except for retinopathy. The primary outcome was death before discharge and/or threshold retinopathy. Threshold retinopathy of prematurity (New Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18]) was coded if any of the following findings were present up to 55 weeks post-menstrual age:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic interventions defined as any of the following: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, vitrectomy, and bevacizumab (Avastin).

Other outcomes recorded included only predefined clinical diagnoses and potential adverse events.

Statistical analysis

The primary analysis for the oxygen saturation arm of this factorial trial was a generalized estimating equation (GEE) model that used robust Poisson regression to produce adjusted relative risks comparing incidence rates for infants in each treatment arm who developed the primary outcome. The model produces relative risk estimates adjusted for stratification by center and gestational age as well as for

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

familial clustering due to randomization of multiple births to the same treatment arm. A median actual oxygen saturation value while on oxygen supplementation was determined for each infant to compare the effect of targeting an actual oxygen saturation value between treatment arms.

An absolute difference of 10% between the two treatment groups was considered clinically important. The sample size calculations were based on the rate of death or threshold retinopathy of 50% in the Neonatal Research Network from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or neurodevelopmental impairment at 18-22 months corrected age). Based on an intracluster correlation of 0.12 in this outcome, the sample size was increased by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because this introduced a clustering effect into the design. The required sample size was increased by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the two factorial arms.

Intent-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. A two-sided p value of less than 0.05 was considered to be statistically significant. Analyses did not include adjustment for multiple comparisons. An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at ~25%, 50%, and 75% of planned enrollment. In addition, the Data Safety and Monitoring Committee, upon request of the investigators, evaluated the oxygen saturation data after enrollment of ____ infants to evaluate

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

compliance with the protocol. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of the above events.

RESULTS

1316 infants were enrolled between January 2004 and March 2009 (Figure 1). Enrollment was temporarily paused after evaluation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and Human Development Director because of concerns regarding compliance with oxygen saturation targets. Separate analysis of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns, and continued enrollment was approved.

The baseline characteristics of the lower saturation group and the higher saturation group were similar (Table 1).

Major outcomes

The primary outcome, threshold retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; p=0.____; Table 2). Death before discharge occurred in 130 of the 654 (20%) of the infants in the lower oxygen saturation group versus in 107 of the 662 (16%) of the infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; p=0.04). Comparable results were observed for both gestational age strata. Kaplan Meier Analysis indicated _____ (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Threshold retinopathy was

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

decreased in the lower oxygen saturation targeted group (9 vs 18%; RR 0.51; CI 0.37, 0.71; p=0._____). Oxygen use at 36 weeks was decreased in the lower oxygen saturation group but bronchopulmonary dysplasia determined by the physiological oxygen saturation test at 36 weeks and the composite outcome of bronchopulmonary dysplasia/death did not differ between the treatment groups. Other pre-specified major outcomes did not differ significantly between the two treatment groups (Table 2).

The median oxygen saturation of both groups differed substantially but, as expected, there was substantial overlap (Figure 3). These data indicate that actual oxygen saturation levels are slightly higher than targets in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Table 3). Other measures of resource utilization did not differ as well.

DISCUSSION

The recommended ranges of oxygen saturation targeting for very preterm infants have been determined from non-randomized studies, and restriction of oxygen supplementation is becoming the common practice.[3-5, 19] However, there was an increase in mortality when a restrictive oxygen supplementation was practiced in the 1950s and 1960s. Despite not being based on randomized controlled trials and the limited evidence of safety, lower oxygen saturation targeting has been increasingly adopted by units and physicians in an attempt to decrease retinopathy of prematurity. However, in this large multicenter randomized trial we found that even though lower oxygen saturation targeting reduced threshold retinopathy, it also increased the risk for mortality.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

This trial was not powered to examine a difference in mortality only between the two oxygen saturation groups. However, this is the largest completed prospective multi-center randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results add to previous data raising the concern that oxygen restriction may increase mortality in very preterm infants. The infants in this trial were more immature than those of any previous trials of oxygen restriction and, thus, may have had a higher susceptibility to the effects of lower oxygen saturation targeting. The previous data on the increased mortality from oxygen restriction were from studies with lower levels of evidence rather than from randomized controlled trials. It is interesting and worrisome that the combined risk difference observed in the trials from the1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.8% mortality increase in the lower targeted SpO2 group that was observed in our trial.

Restriction of oxygenation controlled trials in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17, 20] However, these trials aimed for saturations of 91 to 94% and 89 to 94% in the lower oxygen saturation group which are closer to the targets of the higher saturation arm in the current trial. The lower target of oxygen saturations or the use of the intervention starting at birth and continuing while oxygen supplementation was needed in the current trial may be related to the adverse outcome.

Recent meta-analyses of trials of restriction of oxygen supplementation based on trials conducted in the 1950s to the 1970s showed a large reduction in severe retinopathy (RR 0.19; CI 0.07, 0.50).[1,21] There

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

have not been other randomized controlled trials of different oxygen targeting starting soon after birth to reduce retinopathy. However, results of most non-randomized studies show that lower oxygen saturation targeting reduces retinopathy of prematurity. The current trial confirmed that lower oxygen targeting results in a large reduction of severe retinopathy.

In summary, lower oxygen saturation targeting did not affect the combined outcome of threshold retinopathy/death but increased mortality and decreased threshold retinopathy. There are several ongoing trials across the world that address the same intervention tested in the current trial as well as a planned prospective meta-analysis.[22] These trials use the same algorithms for oxygen saturation targeting so their data will be easy to combine in a meta-analysis to determine short and long term effects of oxygen saturation targeting. At the present time, it is important that these trials continue and that the investigators and the data safety and monitoring committees of these trials are aware of the results of the current trial so that appropriate decisions can be made regarding their interim analyses, completion of the trials, and dissemination of the data. The current trial raises the concern of adverse hospital outcomes due to oxygen saturation targeting in the 85 to 89% range. Neurodevelopmental assessments are being performed at 18-22 months corrected age. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years but at the present time, caution should be exercised regarding oxygen targeting in the low range for extremely premature babies, such as those tested in the current trial.

Those papers were the ones that both you and Neil sent. Can you and Neil hit "reply all" and resend the papers from your computers? I think this is a word 2007 issue.

Otherwise - can resend them on Monday once I have a patch installed by our IT folks for word 2007

Sorry for the trouble.
Av is the only one who asked for Figures. Ed bell had trouble opening the documents

Thanks
Rose

Hi Ed, Av, Jon and David,
You were included on the previous email and I am writing to ask a big favor.

We would like you to consider doing an internal review for these papers and providing me with written comments by 3 PM on 11/16. Let me know if your schedule permits. If you are not able to meet the time frame planned, let me know. There is urgency to submission of the papers.

Thanks in advance!!!
Rose

Hi,
Attached are the two papers in draft form for the SUPPORT Primary outcomes. As noted, there is an increase in death in the lower saturation group (20%) versus the higher saturation group (16%).

This information is confidential and a plan is in place for DSMC communication with ongoing trials of oxygen saturation. If you are contacted by any investigators from other trials or elsewhere, do not share this information. If necessary, refer them to me.

The plan for submission is as follows:

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

November 16 – 4 PM – call for Steering committee and authors to discuss papers. In the meantime, feel free to send comments to Neil and Wally. The call in number is:
866-675-(b) (6) with passcode (b) (6)

If you are not going to be on the call, send comments in advance or designate someone to serve in your absence.

Immediately following the call, the manuscripts will be finalized for NICHD clearance and for submission to the New England Journal of Medicine.

Thanks in advance to everyone for all their hard work!!!

Hi Wally
I would not stress over this
I would suggest the following:
All surviving infants were followed by opthalmological specialists familiar with ROP until they had mature retina or until any observed ROP was deemed to have become quiescent or whatever wording is acceptable

We don't need to set a length in PCA
Neil

Attachments: T2S Major Outcomes - 06NOV09.doc; T3S Other Outcomes - 06NOV09.doc.rtf; Cause of Death - 06NOV09.doc.rtf; T1S Baseline Characteristics - 06NOV09.doc.rtf

See below for some answers (in green). Others I'm still working on. New tables 1, 2, and 3 are attached, as are tables for cause of death (Table
1 and COD table have unadjusted p-values, all other p-values for outcomes are adjusted). Note that the DSMC was concerned about the "other" COD category. These are mostly cases where a terminal event rather than an underlying cause of death was recorded on the GDB forms.
We may have to query the centers to obtain more information. See the end of the COD document attached for "other" causes that have been moved into other categories, as well as those that are still in the "other"
category of the table. Please let me know if any adjustments to these categories need to be made. I have not updated any numbers in the text of Wally's paper yet, but I'll work on that and the other outstanding issues this weekend.

I have no problem with including that figure in a supplemental appendix.

Thanks

Dear Rose, Neil, Marie and Abhik:

I have enclosed responses to Rose's comment below (red). I also incorporated Abhik's.

Abhik and Marie:

There are a few requests for you.

Thanks Wally

Wally

Thanks for quickly turning this around.

We refer ro nonrandomized studies in several sections of the paper. Is observational a better word?

Sometimes "observational" may be ok but most studies were pre post studies (following a change in oxygen saturation targeting). These studies could be called "controlled" which is a better level of evidence than observational. I have been more specific in how I refer to those studies in the revised draft.

There is no citation of the STOP-ROP paper in the manuscript. Although this looked at saturation levels in pretheshold ROP, it should probably be listed.

It was quoted (ref 20) but the incorrect reference was put inadvertently in the reference list. This is now corrected. If we are below the NEJM word limit, I can add more details (especially that the intervention was late in the hospital course).

Methods - end of the first paragraph - delete "before delivery" as part of the consent process. Although this occrred in the vast majority, there were a few that occurred after delivery for a variety of reasons.

This happened because the protocol allowed it. I was trying to keep it short so may omit the details (exception).

Wold it be possible to include the scatter graph of actual versus monitor oximetry levels included in the stdy protocl in the supplementary/appendix materials? We explain this 3 percent offset in the methods on page 12, bt the graph really shows it to those who are visually oriented.

Abhik: What do you think?

At the bottom of page 12 we stated that sat targets were maintained by "clinicians.". It may be more accurate to say adjustments.... were performed by "NICU or clinical staff.". This way, everyone (nrse, md, resp therapist) are included and it is acucrate reporting.

Agree, change made.

In the methods section (page 13) nder assessments - should we (or do we even have space) report abot the 14 day safety monitoring??

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Rose: What should I say about the 14 day safety monitoring?

Leave 18-22 month FU out of the methods section on page 13 I this shold be incluuded in the discussion.

Moved to the Discussion section as suggested.

Bottom of page 14 I should we add one sentence about the first dsmc look at the data that occurred due to concern with compliance with sat levels are the part of the investigators as this happened prior to 25 percent enrollment? I suggest "dsmc evaluated sat data upon reqest of investigators to evaluate compliance after enrollment of XX infants.".
You do explain this in the results and it leaves the reader wondering why we did this.

Done

Results - first line page 15 I enrollment started in Feb 2005 not Jan 2004 (I think).

Marie: Can you check?

MG: First enrolled infant was in Feb 2005

Discussion - second line - you stated "standard" practice. I recommend changing this to "common" practice as there was no AAP guideline or otherwise indicating "standard."

Done

Page 17 - end paragraph- reviewers may want to know abot the lower sat infants and deaths (ron goldberg's comment at the sc meeting.

I think this will need further explanatory analysis. We may be able to address with Kaplan Meier plot and cause of deaths (which I have requested to Marie).

The last paragraph of the discussion should restate the primary outcome and the two significant otcones of ROP and BPD benefit.

Done, except BPD was only decreased when analyzed by O2 weaning, not by physiologic definition and the competing outcome of death eliminated the BPD benefit. Thus, I have not emphasized a BPD benefit.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Table 1 has 655 in low sat group and 661 in high sat group. On table 2 many of the denominators are 654 in low sat group and there is a denominator of 662 on several of the high sat outcomes - we need to fix this.

Marie: Can you correct these? Can you also verify the figure numbers?

Also, threshold rop/death says 17/605 for low sat group (should be 170/) and high sat group says 198.616.

Corrected

Figure 1 - is there a way to have "pregnancies" assessed for eligibility?". That is actually how this nfolded.

Marie: Please check.

MG: We could convert certain numbers to pregnancies, but one of the problems is that those numbers are terrible to begin with. They do not account for pregnancies that were screened but did not result in deliveries that made it into the GDB or SUPPORT. If we want to give readers an accurate picture of how many women were screened/eligible we would be better off citing numbers from the Antenatal Consent study.

For figure 2 - is there any way to "statistically" assess if we reached an adequate separation between the two groups??
Marie: Can you analyze? I am sure they are statistically significant.

MG: A Rank Sums test of the difference of the medians of the two distributions in Figure 2 has a p-value of <0.0001.

Also -
I also pulled the May 2009 NeoProm confidential update.
As of that meeting, the following nmbers were recruited into the trials:

BOOST II australia 658/1200
BOOST II New zealand -291/320
BOOST UK -332/1200
COT -684/1200

Each trial has a dsmc and likely monitoring AE's like mortality. I have spoken to NICHD and NHLBI leadership. The other trials are enrolling children following delivery. Our dsmc meets Nov 4 -the leadership would like input from or DSMC prior to any possible confidential dscussions with other dsmc's. Also the observed mortality between the two sat groups (16 and 20 percent) is tighter than the nrn range of mortality from historical data provided to our dsmc (9.5-32 percent deaths by day 14).

Dear Rose, Neil, Marie and Abhik:

Enclosed is the next draft. I have received comments from some of you and from Michele, and I have responded to the issues raised.

I talked with Abhik and he agreed Marie should get a Kaplan Meier plot for mortality (New Fig 2).

I think it is ready to be sent to the rest of the Subcommittee.

	6=Immaturity	5/85 (6)	3/73 (4)	
	7=Other	6/85 (7)	12/73 (16)	

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Cause of Death for Low vs. High SpO2
Where GA is 26-27 weeks

Variable	Category	Low SpO2 (N=45)	High SpO2 (N=34)	Unadjusted P-value
Contributory cause of death (NG03e, NG03, NG05)	1=RDS	8/45 (18)	10/34 (29)	0.4182
	2=BPD	6/45 (13)	1/34 (3)	
	3=Infection	9/45 (20)	8/34 (24)	
	4=NEC	6/45 (13)	5/34 (15)	
	5=CNS Insult	2/45 (4)	3/34 (9)	
	6=Immaturity	2/45 (4)	0/34 (0)	
	7=Other	12/45 (27)	7/34 (21)	

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Contributory cause of death (NG03e, NG03, NG05)=1=RDS

Obs	Other COD specified on NG03e, NG03 or NG05
1	extreme prematurity, RDS, suspected sepsis

Contributory cause of death (NG03e, NG03, NG05)=2=BPD

Obs	Other COD specified on NG03e, NG03 or NG05
2	bpd with multi-systaem organ failure,developed abd. compartment syndrome post-op stricture repair
3	Early onset sepsis & BPD w/severe intracranial hemorrhage.
4	PAHN, Liver Failure, CLD, Resp Failure
5	Endocarditis, Staph pneumonia, multiple pneumothoraces, cystic abscess in lung and advanced BPD
6	Cardiopulmonary arrest due to Pulmonary hypertension & Systemic hypotension & chronic lung disease

Contributory cause of death (NG03e, NG03, NG05)=3=Infection

Obs	Other COD specified on NG03e, NG03 or NG05
7	disseminated Candidiasis
8	pneumonia, sepsis (Blood and lung cultures (+) for S. Aureus, E. Cloacae)
9	proven NEC, sepsis, extreme prematurity
10	extreme prematurity, suspected pulmonary hypoplasia, pneumonia, presumed sepsis
11	ELBW, acute renal failure, severe lung disease, pneumonia, proven sepsis, hypocalcemia
12	septic shock, cardio-respiratory failure, renal failure
13	extreme prematurity, and sepsis
14	extreme prematurity, ecoli sepsis,meningitis
15	Pseudomonas sepsis, acute resp. failure, renal failure
16	pulmonary hypoplasia, clinical sepsis
17	suspected sepsis, DIC, and cerebellar hemorrhage
18	bilateral chylothoraces, sepsis, meconium peritonitis

Contributory cause of death (NG03e, NG03, NG05)=5=CNS Insult

Obs	Other COD specified on NG03e, NG03 or NG05
19	Severe IVH, Pulmonary hemorrhage, HMD, PIE
20	Severe IVH and Pulmonary Hemorrhage
21	Pulmonary hypoplasia with severe intraparenchymal IVH
22	Renal failure and Intraventricular hemorrhage

Contributory cause of death (NG03e, NG03, NG05)=6=Immaturity

Obs	Other COD specified on NG03e, NG03 or NG05
23	severe IUGR
24	prematurity, pulmonary hypertension,cardiorespiratory failure
25	extreme prematurity, severe pulmonary insufficiency

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Other causes of death specified by current classification in COD table

Contributory cause of death (NG03e, NG03, NG05)=7=Other

Obs	Other COD specified on NG03e, NG03 or NG05
26	extensive hemorrhage mid brain,brain stem,thalamic with uncal herniation and hydrocephaly
27	Respiratory failure
28	Pulmonary hemorrhage
29	liver failure
30	renal failure; DIC
31	liver failure with bleeding; ost. sites
32	PPHN-persistent pulmonary hypertension of neonate
33	intravascular hemorrhage before birth
34	per autopsy cause is exsanguination
35	pulmonary hypertension, pulmonary hypoplasia
36	pulmonary hypoplasia, chroramnionitis
37	Pulmonary Hypoplasia
38	twin to twin transfusion syndrome
39	massive pulmonary hemorrhage
40	pulmonary hemorrhage
41	pulmonary hypoplasia
42	Lung hypoplasia
43	hypoplastic lung syndrome due to pprom
44	Massive pulmonary hemorrhage without RDS
45	pulmonary hypoplasia due to multiple congenital anomalies
46	MULTI SYSTEM ORGAN FAILURE
47	severe hypoplastic lungs
48	renal failure;
49	severe pulmonary hypertension
50	tetralogy of fallot 7 other multiple cardiac anomalies renal anomalies(possiblby va cterl syndrome
51	cardiac arrythmia
52	extensive hemorrhage of rt. chest cavity after chest tube placement
53	perforation of right atrium by tip of PICC line
54	transposition of the great vessels
55	PREMATURITY, PULMONARY HYPOPLESIA, EXOPHAGEAL ATRESIA, SKELETAL ANNOMALIES
56	probable pulmonary hypoplasia

Subject: Oxygen Saturation paper for your comments.

Dear SUPPORT Subcommittee members:

Enclosed is a draft of the oxygen saturation paper for your comments. I need everyone's comments before we can submit to the Publications Subcommittee and the whole Steering Committee which gets it at the same time. I am also enclosing the first draft of the PAS abstract which is currently slightly above the word limit.

Wally

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Case Western Reserve University Rainbow Babies & Children's Hospital (GCRC M01 RR80, U10 HD21364) – Michele C. Walsh, MD MS; Avroy A. Fanaroff, MD; Nancy S. Newman, RN; Bonnie S. Siner, RN.

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95%. The primary outcome was a composite of threshold retinopathy of prematurity and/or death.

Results

Threshold retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; p= ___). Death was more frequent in the lower oxygen saturation target group (20 vs 16%; RR 1.27; CI 1.01, 1.60; p= 0.__) while threshold retinopathy occurred less often in these infants (9 vs 18%; RR 0.51; CI 0.37, 0.71; p= ___).

Conclusions

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcome of threshold retinopathy/death but resulted in an increase in mortality that partially offset a decrease in threshold retinopathy. The increased mortality is of concern as lower saturation targeting is increasingly

being advocated because of its short term retinopathy benefits (Clinical Trials Gov. Number, NCT 00233324).

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] However, in subsequent years, the practice of restricting oxygen supplementation was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6, 7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy[12], and other morbidities. Although a multicenter study [13] could not determine an association between oxygen levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations of lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3,4,5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery was higher in infants cared for in neonatal intensive care units with maximum target oxygen saturation $\geq$ 92% (3.3 $\pm$ 0.3 versus 1.4 $\pm$ 0.2%) or $\geq$ 98% (5.6 $\pm$ 1.1 versus 3.1 $\pm$ 0.3%).[5] The incidence of severe retinopathy requiring ablation therapy was 27% in units where target saturations were 88 to 98% and only 6% in units where the target was 70 to 90% in a retrospective study comparing outcomes at five neonatal intensive care units.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

to 95% resulted in a substantial reduction in retinopathy.[4, 15, 16] However, actual oxygen saturations achieved were not reported. Furthermore, mortality and neurodevelopmental outcomes were not reported. While data from these recent prospective observational studies, retrospective studies, or controlled but not randomized studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease the incidence of retinopathy of prematurity, there is no conclusive evidence that these oxygenation levels do so without an increase in serious adverse effects, including the possibility of increased risk of death with lower oxygenation as previously reported.

We conducted a 2 x 2 factorial-design multicenter randomized trial of oxygen saturation targeting and protocol-driven limited ventilator strategy. The oxygen saturation part of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of threshold retinopathy of prematurity or death among infants of 24 to 27 weeks gestational age at birth. The ventilation part of this factorial design trial was used to control for the ventilatory approach and test other hypotheses and will be reported separately.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at RTI, the independent data coordinating center, approved the trial. Written informed consent was obtained from the parent or guardian of each participant before delivery.

Patients

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation for which a decision had been made to provide full resuscitation were eligible for enrollment at birth. Outborn infants and major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of double-sealed opaque envelopes to oxygen saturation targeting of 85 to 89% or 91 to 95% (the lower and higher oxygen saturation target groups, respectively) using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88 to 92% for these oxygen ranges, with an offset of 3% (Massimo Radical Set Pulse Oximeter, Irvine, CA) as previously used to separate oxygen saturations in premature infants.[17] Thus, for example, an oxygen saturation display of 92% would correspond to an actual oxygen saturation of 89% and 95% in the 85-89% and 91-95% target groups, respectively. The oxygen saturation values displayed reverted to actual values when less than 85% or higher than 95%, the levels of alarm setting recommended in the protocol. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours. Infants weaned to room air but who subsequently received oxygen supplementation before 36 weeks post-menstrual age were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinical, not the research staff. Reports of displayed data by clinical center were provided quarterly for feedback on targeting performance. For the ventilation part of this 2 by 2

factorial design trial, participants were also randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilation strategy.

Assessments

Research nurses recorded all data using standardized definitions included in the trial Manual of Operations. Data were collected until discharge except for retinopathy. The primary outcome was death before discharge and/or threshold retinopathy. Threshold retinopathy of prematurity (New Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18]) was coded if any of the following findings were present up to 55 weeks post-menstrual age:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic interventions defined as any of the following: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, vitrectomy, and bevacizumab (Avastin).

Other outcomes recorded included only predefined clinical diagnoses and potential adverse events.

Statistical analysis

The primary analysis for the oxygen saturation arm of this factorial trial was a generalized estimating equation (GEE) model that used robust Poisson regression to produce adjusted relative risks comparing incidence rates for infants in each treatment arm who developed the primary outcome. The model produces relative risk estimates adjusted for stratification by center and gestational age as well as for

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

familial clustering due to randomization of multiple births to the same treatment arm. A median actual oxygen saturation value while on oxygen supplementation was determined for each infant to compare the effect of targeting an actual oxygen saturation value between treatment arms.

An absolute difference of 10% between the two treatment groups was considered clinically important. The sample size calculations were based on the rate of death or threshold retinopathy of 50% in the Neonatal Research Network from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or neurodevelopmental impairment at 18-22 months corrected age). Based on an intracluster correlation of 0.12 in this outcome, the sample size was increased by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because this introduced a clustering effect into the design. The required sample size was increased by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the two factorial arms.

Intent-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. A two-sided p value of less than 0.05 was considered to be statistically significant. Analyses did not include adjustment for multiple comparisons. An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at ~25%, 50%, and 75% of planned enrollment. In addition, the Data Safety and Monitoring Committee, upon request of the investigators, evaluated the oxygen saturation data after enrollment of ____ infants to evaluate

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

compliance with the protocol. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of the above events.

RESULTS

1316 infants were enrolled between January 2004 and March 2009 (Figure 1). Enrollment was temporarily paused after evaluation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and Human Development Director because of concerns regarding compliance with oxygen saturation targets. Separate analysis of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns, and continued enrollment was approved.

The baseline characteristics of the lower saturation group and the higher saturation group were similar (Table 1).

Major outcomes

The primary outcome, threshold retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; p=0.____; Table 2). Death before discharge occurred in 130 of the 654 (20%) of the infants in the lower oxygen saturation group versus in 107 of the 662 (16%) of the infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; p=0.04). Comparable results were observed for both gestational age strata. Kaplan Meier Analysis indicated _____ (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Threshold retinopathy was

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

decreased in the lower oxygen saturation targeted group (9 vs 18%; RR 0.51; CI 0.37, 0.71; p=0._____). Oxygen use at 36 weeks was decreased in the lower oxygen saturation group but bronchopulmonary dysplasia determined by the physiological oxygen saturation test at 36 weeks and the composite outcome of bronchopulmonary dysplasia/death did not differ between the treatment groups. Other pre-specified major outcomes did not differ significantly between the two treatment groups (Table 2).

The median oxygen saturation of both groups differed substantially but, as expected, there was substantial overlap (Figure 3). These data indicate that actual oxygen saturation levels are slightly higher than targets in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Table 3). Other measures of resource utilization did not differ as well.

DISCUSSION

The recommended ranges of oxygen saturation targeting for very preterm infants have been determined from non-randomized studies, and restriction of oxygen supplementation is becoming the common practice.[3-5, 19] However, there was an increase in mortality when a restrictive oxygen supplementation was practiced in the 1950s and 1960s. Despite not being based on randomized controlled trials and the limited evidence of safety, lower oxygen saturation targeting has been increasingly adopted by units and physicians in an attempt to decrease retinopathy of prematurity. However, in this large multicenter randomized trial we found that even though lower oxygen saturation targeting reduced threshold retinopathy, it also increased the risk for mortality.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

This trial was not powered to examine a difference in mortality only between the two oxygen saturation groups. However, this is the largest completed prospective multi-center randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results add to previous data raising the concern that oxygen restriction may increase mortality in very preterm infants. The infants in this trial were more immature than those of any previous trials of oxygen restriction and, thus, may have had a higher susceptibility to the effects of lower oxygen saturation targeting. The previous data on the increased mortality from oxygen restriction were from studies with lower levels of evidence rather than from randomized controlled trials. It is interesting and worrisome that the combined risk difference observed in the trials from the1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.8% mortality increase in the lower targeted SpO2 group that was observed in our trial.

Restriction of oxygenation controlled trials in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17, 20] However, these trials aimed for saturations of 91 to 94% and 89 to 94% in the lower oxygen saturation group which are closer to the targets of the higher saturation arm in the current trial. The lower target of oxygen saturations or the use of the intervention starting at birth and continuing while oxygen supplementation was needed in the current trial may be related to the adverse outcome.

Recent meta-analyses of trials of restriction of oxygen supplementation based on trials conducted in the 1950s to the 1970s showed a large reduction in severe retinopathy (RR 0.19; CI 0.07, 0.50).[1,21] There

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

have not been other randomized controlled trials of different oxygen targeting starting soon after birth to reduce retinopathy. However, results of most non-randomized studies show that lower oxygen saturation targeting reduces retinopathy of prematurity. The current trial confirmed that lower oxygen targeting results in a large reduction of severe retinopathy.

In summary, lower oxygen saturation targeting did not affect the combined outcome of threshold retinopathy/death but increased mortality and decreased threshold retinopathy. There are several ongoing trials across the world that address the same intervention tested in the current trial as well as a planned prospective meta-analysis.[22] These trials use the same algorithms for oxygen saturation targeting so their data will be easy to combine in a meta-analysis to determine short and long term effects of oxygen saturation targeting. At the present time, it is important that these trials continue and that the investigators and the data safety and monitoring committees of these trials are aware of the results of the current trial so that appropriate decisions can be made regarding their interim analyses, completion of the trials, and dissemination of the data. The current trial raises the concern of adverse hospital outcomes due to oxygen saturation targeting in the 85 to 89% range. Neurodevelopmental assessments are being performed at 18-22 months corrected age. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years but at the present time, caution should be exercised regarding oxygen targeting in the low range for extremely premature babies, such as those tested in the current trial.

Title: Randomized Trial of Oxygen Saturation Targets in Premature Infants.

W.A. Carlo for the SUPPORT Subcommittee of the NICHD Neonatal Research Network.

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, it is important to determine if lower oxygen saturation targets reduce retinopathy without increasing adverse outcomes.

Objective

To test the hypothesis that a lower oxygen saturation target decreases threshold retinopathy or deaths in extremely premature infants.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95% using masked oximeters. The primary outcome was a composite of threshold retinopathy of prematurity and/or death.

-

Results

Threshold retinopathy/death did not differ between the oxygen saturation target groups (Table). Threshold retinopathy was decreased ($P<0.05$) in the lower oxygen saturation target group but death was more frequent ($P<0.05$, Table). Oxygen use at 36 weeks decreased in the lower oxygen

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

saturation target group but oxygen use by the physiologic definition or oxygen use at 36 weeks/death did not decrease. Other outcomes did not differ between the groups.

Conclusions

Lower oxygen saturation (85-89%) targets did not significantly decrease the combined outcomes of threshold retinopathy/death but resulted in an increase in mortality that partially offset a decrease in threshold retinopathy. The increased mortality is of concern as lower saturation targeting is increasingly being advocated because it has short term retinopathy benefits.

Table:

	Lower Saturation Group n/N (%)	Higher Saturation Group n/N (%)	Adjusted Relative Risk[1] (95% CI)
Threshold retinopathy/death	170/605 (28)	198/616 (32)	0.90 (0.76, 1.06)
Threshold retinopathy	43/483 (9)	95/514 (18)	0.51 (0.37, 0.71)
Death before discharge	130/654 (20)	107/662 (16)	1.27 (1.01, 1.60)
Bronchopulmonary dysplasia by O_2 use at 36 weeks*	202/540 (37)	265/568 (47)	0.81 (0.71, 0.92)
Bronchopulmonary dysplasia (O_2 use) or death by 36 weeks*	316/654 (48)	359/662 (54)	0.91 (0.82, 1.01)
Bronchopulmonary dysplasia (physiologic) at 36 weeks*	205/540 (38)	237/568 (42)	0.92 (0.81, 1.05)
Intraventricular hemorrhage, grade 3 or 4	83/630 (13)	81/640 (13)	1.06 (0.80, 1.40)
Necrotizing enterocolitis, stage ≥ 2	76/641 (12)	70/649 (11)	1.11 (0.82, 1.51)
Late onset sepsis	228/624 (37)	226/634 (36)	1.03 (0.89, 1.18)
Patent ductus arteriosus	307/641 (48)	324/648 (50)	0.96 (0.86, 1.07)

Hi Ed, Av, Jon and David,
You were included on the previous email and I am writing to ask a big favor.

We would like you to consider doing an internal review for these papers and providing me with written comments by 3 PM on 11/16. Let me know if your schedule permits. If you are not able to meet the time frame planned, let me know. There is urgency to submission of the papers.

Thanks in advance!!!
Rose

Subject: ****CONFIDENTIAL SUPPORT DRAFT MANUSCRIPTS*******

Hi,
Attached are the two papers in draft form for the SUPPORT Primary outcomes. As noted, there is an increase in death in the lower saturation group (20%) versus the higher saturation group (16%).

This information is confidential and a plan is in place for DSMC communication with ongoing trials of oxygen saturation. If you are contacted by any investigators from other trials or elsewhere, do not share this information. If necessary, refer them to me.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The plan for submission is as follows:
November 16 - 4 PM - call for Steering committee and authors to discuss papers. In the meantime, feel free to send comments to Neil and Wally. The call in number is:
866-675-(b) (6) with passcode (b) (6)

If you are not going to be on the call, send comments in advance or designate someone to serve in your absence.

Immediately following the call, the manuscripts will be finalized for NICHD clearance and for submission to the New England Journal of Medicine.

Thanks in advance to everyone for all their hard work!!!
Rose

Wally
I am fine with this with the exception of the primary outcome numbers - the denominators add up to 1321 infants - this is NOT correct - can Marie check all the numbers in the table??
Thanks
Rose

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95%. The primary outcome was a composite of threshold retinopathy of prematurity and/or death.

Results

Threshold retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; p= ___). Death was more frequent in the lower oxygen saturation target group (20 vs 16%; RR 1.27; CI 1.01, 1.60; p= 0.__) while threshold retinopathy occurred less often in these infants (9 vs 18%; RR 0.51; CI 0.37, 0.71; p= ___).

Conclusions

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcome of threshold retinopathy/death but resulted in an increase in mortality that partially offset a decrease in threshold retinopathy. The increased mortality is of concern as lower saturation targeting is increasingly

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] However, in subsequent years, the practice of restricting oxygen supplementation was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6, 7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy[12], and other morbidities. Although a multicenter study [13] could not determine an association between oxygen levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations of lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3,4,5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery was higher in infants cared for in neonatal intensive care units with maximum target oxygen saturation $\geq$ 92% (3.3 $\pm$ 0.3 versus 1.4 $\pm$ 0.2%) or $\geq$ 98% (5.6 $\pm$ 1.1 versus 3.1 $\pm$ 0.3%).[5] The incidence of severe retinopathy requiring ablation therapy was 27% in units where target saturations were 88 to 98% and only 6% in units where the target was 70 to 90% in a retrospective study comparing outcomes at five neonatal intensive care units.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

to 95% resulted in a substantial reduction in retinopathy.[4, 15, 16] However, actual oxygen saturations achieved were not reported. Furthermore, mortality and neurodevelopmental outcomes were not reported. While data from these recent prospective observational studies, retrospective studies, or controlled but not randomized studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease the incidence of retinopathy of prematurity, there is no conclusive evidence that these oxygenation levels do so without an increase in serious adverse effects, including the possibility of increased risk of death with lower oxygenation as previously reported.

We conducted a 2 x 2 factorial-design multicenter randomized trial of oxygen saturation targeting and protocol-driven limited ventilator strategy. The oxygen saturation part of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of threshold retinopathy of prematurity or death among infants of 24 to 27 weeks gestational age at birth. The ventilation part of this factorial design trial was used to control for the ventilatory approach and test other hypotheses and will be reported separately.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at RTI, the independent data coordinating center, approved the trial. Written informed consent was obtained from the parent or guardian of each participant before delivery.

Patients

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation for which a decision had been made to provide full resuscitation were eligible for enrollment at birth. Outborn infants and major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of double-sealed opaque envelopes to oxygen saturation targeting of 85 to 89% or 91 to 95% (the lower and higher oxygen saturation target groups, respectively) using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88 to 92% for these oxygen ranges, with an offset of 3% (Massimo Radical Set Pulse Oximeter, Irvine, CA) as previously used to separate oxygen saturations in premature infants.[17] Thus, for example, an oxygen saturation display of 92% would correspond to an actual oxygen saturation of 89% and 95% in the 85-89% and 91-95% target groups, respectively. The oxygen saturation values displayed reverted to actual values when less than 85% or higher than 95%, the levels of alarm setting recommended in the protocol. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours. Infants weaned to room air but who subsequently received oxygen supplementation before 36 weeks post-menstrual age were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinical, not the research staff. Reports of displayed data by clinical center were provided quarterly for feedback on targeting performance. For the ventilation part of this 2 by 2

factorial design trial, participants were also randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilation strategy.

Assessments

Research nurses recorded all data using standardized definitions included in the trial Manual of Operations. Data were collected until discharge except for retinopathy. The primary outcome was death before discharge and/or threshold retinopathy. Threshold retinopathy of prematurity (New Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18]) was coded if any of the following findings were present up to 55 weeks post-menstrual age:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic interventions defined as any of the following: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, vitrectomy, and bevacizumab (Avastin).

Other outcomes recorded included only predefined clinical diagnoses and potential adverse events.

Statistical analysis

The primary analysis for the oxygen saturation arm of this factorial trial was a generalized estimating equation (GEE) model that used robust Poisson regression to produce adjusted relative risks comparing incidence rates for infants in each treatment arm who developed the primary outcome. The model produces relative risk estimates adjusted for stratification by center and gestational age as well as for

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

familial clustering due to randomization of multiple births to the same treatment arm. A median actual oxygen saturation value while on oxygen supplementation was determined for each infant to compare the effect of targeting an actual oxygen saturation value between treatment arms.

An absolute difference of 10% between the two treatment groups was considered clinically important. The sample size calculations were based on the rate of death or threshold retinopathy of 50% in the Neonatal Research Network from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or neurodevelopmental impairment at 18-22 months corrected age). Based on an intracluster correlation of 0.12 in this outcome, the sample size was increased by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because this introduced a clustering effect into the design. The required sample size was increased by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the two factorial arms.

Intent-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. A two-sided p value of less than 0.05 was considered to be statistically significant. Analyses did not include adjustment for multiple comparisons. An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at ~25%, 50%, and 75% of planned enrollment. In addition, the Data Safety and Monitoring Committee, upon request of the investigators, evaluated the oxygen saturation data after enrollment of ____ infants to evaluate

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

compliance with the protocol. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of the above events.

RESULTS

1316 infants were enrolled between January 2004 and March 2009 (Figure 1). Enrollment was temporarily paused after evaluation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and Human Development Director because of concerns regarding compliance with oxygen saturation targets. Separate analysis of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns, and continued enrollment was approved.

The baseline characteristics of the lower saturation group and the higher saturation group were similar (Table 1).

Major outcomes

The primary outcome, threshold retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; p=0.____; Table 2). Death before discharge occurred in 130 of the 654 (20%) of the infants in the lower oxygen saturation group versus in 107 of the 662 (16%) of the infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; p=0.04). Comparable results were observed for both gestational age strata. Kaplan Meier Analysis indicated _____ (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Threshold retinopathy was

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

decreased in the lower oxygen saturation targeted group (9 vs 18%; RR 0.51; CI 0.37, 0.71; p=0._____). Oxygen use at 36 weeks was decreased in the lower oxygen saturation group but bronchopulmonary dysplasia determined by the physiological oxygen saturation test at 36 weeks and the composite outcome of bronchopulmonary dysplasia/death did not differ between the treatment groups. Other pre-specified major outcomes did not differ significantly between the two treatment groups (Table 2).

The median oxygen saturation of both groups differed substantially but, as expected, there was substantial overlap (Figure 3). These data indicate that actual oxygen saturation levels are slightly higher than targets in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Table 3). Other measures of resource utilization did not differ as well.

DISCUSSION

The recommended ranges of oxygen saturation targeting for very preterm infants have been determined from non-randomized studies, and restriction of oxygen supplementation is becoming the common practice.[3-5, 19] However, there was an increase in mortality when a restrictive oxygen supplementation was practiced in the 1950s and 1960s. Despite not being based on randomized controlled trials and the limited evidence of safety, lower oxygen saturation targeting has been increasingly adopted by units and physicians in an attempt to decrease retinopathy of prematurity. However, in this large multicenter randomized trial we found that even though lower oxygen saturation targeting reduced threshold retinopathy, it also increased the risk for mortality.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

This trial was not powered to examine a difference in mortality only between the two oxygen saturation groups. However, this is the largest completed prospective multi-center randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results add to previous data raising the concern that oxygen restriction may increase mortality in very preterm infants. The infants in this trial were more immature than those of any previous trials of oxygen restriction and, thus, may have had a higher susceptibility to the effects of lower oxygen saturation targeting. The previous data on the increased mortality from oxygen restriction were from studies with lower levels of evidence rather than from randomized controlled trials. It is interesting and worrisome that the combined risk difference observed in the trials from the1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.8% mortality increase in the lower targeted SpO2 group that was observed in our trial.

Restriction of oxygenation controlled trials in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17, 20] However, these trials aimed for saturations of 91 to 94% and 89 to 94% in the lower oxygen saturation group which are closer to the targets of the higher saturation arm in the current trial. The lower target of oxygen saturations or the use of the intervention starting at birth and continuing while oxygen supplementation was needed in the current trial may be related to the adverse outcome.

Recent meta-analyses of trials of restriction of oxygen supplementation based on trials conducted in the 1950s to the 1970s showed a large reduction in severe retinopathy (RR 0.19; CI 0.07, 0.50).[1,21] There

have not been other randomized controlled trials of different oxygen targeting starting soon after birth to reduce retinopathy. However, results of most non-randomized studies show that lower oxygen saturation targeting reduces retinopathy of prematurity. The current trial confirmed that lower oxygen targeting results in a large reduction of severe retinopathy.

In summary, lower oxygen saturation targeting did not affect the combined outcome of threshold retinopathy/death but increased mortality and decreased threshold retinopathy. There are several ongoing trials across the world that address the same intervention tested in the current trial as well as a planned prospective meta-analysis.[22] These trials use the same algorithms for oxygen saturation targeting so their data will be easy to combine in a meta-analysis to determine short and long term effects of oxygen saturation targeting. At the present time, it is important that these trials continue and that the investigators and the data safety and monitoring committees of these trials are aware of the results of the current trial so that appropriate decisions can be made regarding their interim analyses, completion of the trials, and dissemination of the data. The current trial raises the concern of adverse hospital outcomes due to oxygen saturation targeting in the 85 to 89% range. Neurodevelopmental assessments are being performed at 18-22 months corrected age. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years but at the present time, caution should be exercised regarding oxygen targeting in the low range for extremely premature babies, such as those tested in the current trial.

Title: Randomized Trial of Oxygen Saturation Targets in Premature Infants.

W.A. Carlo for the SUPPORT Subcommittee of the NICHD Neonatal Research Network.

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, it is important to determine if lower oxygen saturation targets reduce retinopathy without increasing adverse outcomes.

Objective

To test the hypothesis that a lower oxygen saturation target decreases threshold retinopathy or deaths in extremely premature infants.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95% using masked oximeters. The primary outcome was a composite of threshold retinopathy of prematurity and/or death.

-

Results

Threshold retinopathy/death did not differ between the oxygen saturation target groups (Table). Threshold retinopathy was decreased ($P<0.05$) in the lower oxygen saturation target group but death was more frequent ($P<0.05$, Table). Oxygen use at 36 weeks decreased in the lower oxygen

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

saturation target group but oxygen use by the physiologic definition or oxygen use at 36 weeks/death did not decrease. Other outcomes did not differ between the groups.

Conclusions

Lower oxygen saturation (85-89%) targets did not significantly decrease the combined outcomes of threshold retinopathy/death but resulted in an increase in mortality that partially offset a decrease in threshold retinopathy. The increased mortality is of concern as lower saturation targeting is increasingly being advocated because it has short term retinopathy benefits.

Table:

	Lower Saturation Group n/N (%)	Higher Saturation Group n/N (%)	Adjusted Relative Risk[1] (95% CI)
Threshold retinopathy/death	170/605 (28)	198/616 (32)	0.90 (0.76, 1.06)
Threshold retinopathy	43/483 (9)	95/514 (18)	0.51 (0.37, 0.71)
Death before discharge	130/654 (20)	107/662 (16)	1.27 (1.01, 1.60)
Bronchopulmonary dysplasia by O_2 use at 36 weeks*	202/540 (37)	265/568 (47)	0.81 (0.71, 0.92)
Bronchopulmonary dysplasia (O_2 use) or death by 36 weeks*	316/654 (48)	359/662 (54)	0.91 (0.82, 1.01)
Bronchopulmonary dysplasia (physiologic) at 36 weeks*	205/540 (38)	237/568 (42)	0.92 (0.81, 1.05)
Intraventricular hemorrhage, grade 3 or 4	83/630 (13)	81/640 (13)	1.06 (0.80, 1.40)
Necrotizing enterocolitis, stage ≥ 2	76/641 (12)	70/649 (11)	1.11 (0.82, 1.51)
Late onset sepsis	228/624 (37)	226/634 (36)	1.03 (0.89, 1.18)
Patent ductus arteriosus	307/641 (48)	324/648 (50)	0.96 (0.86, 1.07)

Dear Rose, Neil, Marie and Abhik:

I have enclosed responses to Rose's comment below (red). I also incorporated Abhik's.

Abhik and Marie:
There are a few requests for you.

Thanks Wally

Wally

Thanks for quickly turning this around.

We refer ro nonrandomized studies in several sections of the paper. Is observational a better word?
Sometimes "observational" may be ok but most studies were pre post studies (following a change in oxygen saturation targeting). These studies could be called "controlled" which is a better level of evidence than observational. I have been more specific in how I refer to those studies in the revised draft.

There is no citation of the STOP-ROP paper in the manuscript. Although this looked at saturation levels in pretheshold ROP, it should probably be listed.
It was quoted (ref 20) but the incorrect reference was put inadvertently in the reference list. This is now corrected. If we are below the NEJM word limit, I can add more details (especially that the intervention was late in the hospital course).

Methods - end of the first paragraph - delete "before delivery" as part of the consent process. Although this occrred in the vast majority, there were a few that occurred after delivery for a variety of reasons.
This happened because the protocol allowed it. I was trying to keep it short so may omit the details (exception).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Wold it be possible to include the scatter graph of actual versus monitor oximetry levels included in the stdy protocl in the supplementary/appendix materials? We explain this 3 percent offset in the methods on page 12, bt the graph really shows it to those who are visually oriented.
Abhik: What do you think?

At the bottom of page 12 we stated that sat targets were maintained by "clinicians.". It may be more accurate to say adjustments.... were performed by "NICU or clinical staff.". This way, everyone (nrse, md, resp therapist) are included and it is acucrate reporting.
Agree, change made.

In the methods section (page 13) nder assessments - should we (or do we even have space) report abot the 14 day safety monitoring??
Rose: What should I say about the 14 day safety monitoring?

Leave 18-22 month FU out of the methods section on page 13 I this shold be incluuded in the discussion.
Moved to the Discussion section as suggested.

Bottom of page 14 I should we add one sentence about the first dsmc look at the data that occurred due to concern with compliance with sat levels are the part of the investigators as this happened prior to 25 percent enrollment? I suggest "dsmc evaluated sat data upon reqest of investigators to evaluate compliance after enrollment of XX infants.". You do explain this in the results and it leaves the reader wondering why we did this.
Done

Results - first line page 15 I enrollment started in Feb 2005 not Jan 2004 (I think).

Marie: Can you check?

Discussion - second line - you stated "standard" practice. I recommend changing this to "common" practice as there was no AAP guideline or otherwise indicating "standard."
Done

Page 17 - end paragraph- reviewers may want to know abot the lower sat infants and deaths (ron goldberg's comment at the sc meeting.
I think this will need further explanatory analysis. We may be able to address with Kaplan Meier plot and cause of deaths (which I have requested to Marie).

The last paragraph of the discussion should restate the primary outcome and the two significant otcones of ROP and BPD benefit.
Done, except BPD was only decreased when analyzed by O2 weaning, not by physiologic definition and the competing outcome of death eliminated the BPD benefit. Thus, I have not emphasized a BPD benefit.

Table 1 has 655 in low sat group and 661 in high sat group. On table 2 many of the denominators are 654 in low sat group and there is a denominator of 662 on several of the high sat outcomes - we need to fix this.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Marie: Can you correct these? Can you also verify the figure numbers?

Also, threshold rop/death says 17/605 for low sat group (should be 170/) and high sat group says 198.616.
Corrected

Figure 1 - is there a way to have "pregnancies" assessed for eligibility?". That is actually how this nfolded.
Marie: Please check.

For figure 2 - is there any way to "statistically" assess if we reached an adequate separation between the two groups??
Marie: Can you analyze? I am sure they are statistically significant.

Also -
I also pulled the May 2009 NeoProm confidential update.
As of that meeting, the following nmbers were recruited into the trials:

BOOST II australia 658/1200
BOOST II New zealand -291/320
BOOST UK -332/1200
COT -684/1200

Each trial has a dsmc and likely monitoring AE's like mortality. I have spoken to NICHD and NHLBI leadership. The other trials are enrolling children following delivery. Our dsmc meets Nov 4 -the leadership would like input from or DSMC prior to any possible confidential dscussions with other dsmc's. Also the observed mortality between the two sat groups (16 and 20 percent) is tighter than the nrn range of mortality from historical data provided to our dsmc (9.5-32 percent deaths by day 14).

Dear Rose, Neil, Marie and Abhik:

Enclosed is the next draft. I have received comments from some of you and from Michele, and I have responded to the issues raised.

I talked with Abhik and he agreed Marie should get a Kaplan Meier plot for mortality (New Fig 2).

I think it is ready to be sent to the rest of the Subcommittee.

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95%. The primary outcome was a composite of threshold retinopathy of prematurity and/or death.

Results

Threshold retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; p= ___). Death was more frequent in the lower oxygen saturation target group (20 vs 16%; RR 1.27; CI 1.01, 1.60; p= 0.__) while threshold retinopathy occurred less often in these infants (9 vs 18%; RR 0.51; CI 0.37, 0.71; p= ___).

Conclusions

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcome of threshold retinopathy/death but resulted in an increase in mortality that partially offset a decrease in threshold retinopathy. The increased mortality is of concern as lower saturation targeting is increasingly

being advocated because of its short term retinopathy benefits (Clinical Trials Gov. Number, NCT 00233324).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] However, in subsequent years, the practice of restricting oxygen supplementation was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6, 7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy[12], and other morbidities. Although a multicenter study [13] could not determine an association between oxygen levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations of lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3,4,5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery was higher in infants cared for in neonatal intensive care units with maximum target oxygen saturation $\geq$ 92% (3.3 $\pm$ 0.3 versus 1.4 $\pm$ 0.2%) or $\geq$ 98% (5.6 $\pm$ 1.1 versus 3.1 $\pm$ 0.3%).[5] The incidence of severe retinopathy requiring ablation therapy was 27% in units where target saturations were 88 to 98% and only 6% in units where the target was 70 to 90% in a retrospective study comparing outcomes at five neonatal intensive care units.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

to 95% resulted in a substantial reduction in retinopathy.[4, 15, 16] However, actual oxygen saturations achieved were not reported. Furthermore, mortality and neurodevelopmental outcomes were not reported. While data from these recent prospective observational studies, retrospective studies, or controlled but not randomized studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease the incidence of retinopathy of prematurity, there is no conclusive evidence that these oxygenation levels do so without an increase in serious adverse effects, including the possibility of increased risk of death with lower oxygenation as previously reported.

We conducted a 2 x 2 factorial-design multicenter randomized trial of oxygen saturation targeting and protocol-driven limited ventilator strategy. The oxygen saturation part of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of threshold retinopathy of prematurity or death among infants of 24 to 27 weeks gestational age at birth. The ventilation part of this factorial design trial was used to control for the ventilatory approach and test other hypotheses and will be reported separately.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at RTI, the independent data coordinating center, approved the trial. Written informed consent was obtained from the parent or guardian of each participant before delivery.

Infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation for which a decision had been made to provide full resuscitation were eligible for enrollment at birth. Outborn infants and major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of double-sealed opaque envelopes to oxygen saturation targeting of 85 to 89% or 91 to 95% (the lower and higher oxygen saturation target groups, respectively) using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88 to 92% for these oxygen ranges, with an offset of 3% (Massimo Radical Set Pulse Oximeter, Irvine, CA) as previously used to separate oxygen saturations in premature infants.[17] Thus, for example, an oxygen saturation display of 92% would correspond to an actual oxygen saturation of 89% and 95% in the 85-89% and 91-95% target groups, respectively. The oxygen saturation values displayed reverted to actual values when less than 85% or higher than 95%, the levels of alarm setting recommended in the protocol. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours. Infants weaned to room air but who subsequently received oxygen supplementation before 36 weeks post-menstrual age were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinical, not the research staff. Reports of displayed data by clinical center were provided quarterly for feedback on targeting performance. For the ventilation part of this 2 by 2

factorial design trial, participants were also randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilation strategy.

Assessments

Research nurses recorded all data using standardized definitions included in the trial Manual of Operations. Data were collected until discharge except for retinopathy. The primary outcome was death before discharge and/or threshold retinopathy. Threshold retinopathy of prematurity (New Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18]) was coded if any of the following findings were present up to 55 weeks post-menstrual age:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic interventions defined as any of the following: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, vitrectomy, and bevacizumab (Avastin).

Other outcomes recorded included only predefined clinical diagnoses and potential adverse events.

Statistical analysis

The primary analysis for the oxygen saturation arm of this factorial trial was a generalized estimating equation (GEE) model that used robust Poisson regression to produce adjusted relative risks comparing incidence rates for infants in each treatment arm who developed the primary outcome. The model produces relative risk estimates adjusted for stratification by center and gestational age as well as for

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

familial clustering due to randomization of multiple births to the same treatment arm. A median actual oxygen saturation value while on oxygen supplementation was determined for each infant to compare the effect of targeting an actual oxygen saturation value between treatment arms.

An absolute difference of 10% between the two treatment groups was considered clinically important. The sample size calculations were based on the rate of death or threshold retinopathy of 50% in the Neonatal Research Network from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or neurodevelopmental impairment at 18-22 months corrected age). Based on an intracluster correlation of 0.12 in this outcome, the sample size was increased by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because this introduced a clustering effect into the design. The required sample size was increased by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the two factorial arms.

Intent-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. A two-sided p value of less than 0.05 was considered to be statistically significant. Analyses did not include adjustment for multiple comparisons. An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at ~25%, 50%, and 75% of planned enrollment. In addition, the Data Safety and Monitoring Committee, upon request of the investigators, evaluated the oxygen saturation data after enrollment of ____ infants to evaluate

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

compliance with the protocol. Lan-DeMets spending functions with Pocock and O'Brien-Fleming boundaries were used to develop stopping rules for interim safety and efficacy monitoring, respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of the above events.

RESULTS

1316 infants were enrolled between January 2004 and March 2009 (Figure 1). Enrollment was temporarily paused after evaluation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and Human Development Director because of concerns regarding compliance with oxygen saturation targets. Separate analysis of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns, and continued enrollment was approved.

The baseline characteristics of the lower saturation group and the higher saturation group were similar (Table 1).

Major outcomes

The primary outcome, threshold retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28 vs 32%; RR 0.90; CI 0.76, 1.06; p=0.____; Table 2). Death before discharge occurred in 130 of the 654 (20%) of the infants in the lower oxygen saturation group versus in 107 of the 662 (16%) of the infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; p=0.04). Comparable results were observed for both gestational age strata. Kaplan Meier Analysis indicated _____ (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Threshold retinopathy was

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

decreased in the lower oxygen saturation targeted group (9 vs 18%; RR 0.51; CI 0.37, 0.71; p=0._____). Oxygen use at 36 weeks was decreased in the lower oxygen saturation group but bronchopulmonary dysplasia determined by the physiological oxygen saturation test at 36 weeks and the composite outcome of bronchopulmonary dysplasia/death did not differ between the treatment groups. Other pre-specified major outcomes did not differ significantly between the two treatment groups (Table 2).

The median oxygen saturation of both groups differed substantially but, as expected, there was substantial overlap (Figure 3). These data indicate that actual oxygen saturation levels are slightly higher than targets in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Table 3). Other measures of resource utilization did not differ as well.

DISCUSSION

The recommended ranges of oxygen saturation targeting for very preterm infants have been determined from non-randomized studies, and restriction of oxygen supplementation is becoming the common practice.[3-5, 19] However, there was an increase in mortality when a restrictive oxygen supplementation was practiced in the 1950s and 1960s. Despite not being based on randomized controlled trials and the limited evidence of safety, lower oxygen saturation targeting has been increasingly adopted by units and physicians in an attempt to decrease retinopathy of prematurity. However, in this large multicenter randomized trial we found that even though lower oxygen saturation targeting reduced threshold retinopathy, it also increased the risk for mortality.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

This trial was not powered to examine a difference in mortality only between the two oxygen saturation groups. However, this is the largest completed prospective multi-center randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results add to previous data raising the concern that oxygen restriction may increase mortality in very preterm infants. The infants in this trial were more immature than those of any previous trials of oxygen restriction and, thus, may have had a higher susceptibility to the effects of lower oxygen saturation targeting. The previous data on the increased mortality from oxygen restriction were from studies with lower levels of evidence rather than from randomized controlled trials. It is interesting and worrisome that the combined risk difference observed in the trials from the1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.8% mortality increase in the lower targeted SpO2 group that was observed in our trial.

Restriction of oxygenation controlled trials in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17, 20] However, these trials aimed for saturations of 91 to 94% and 89 to 94% in the lower oxygen saturation group which are closer to the targets of the higher saturation arm in the current trial. The lower target of oxygen saturations or the use of the intervention starting at birth and continuing while oxygen supplementation was needed in the current trial may be related to the adverse outcome.

Recent meta-analyses of trials of restriction of oxygen supplementation based on trials conducted in the 1950s to the 1970s showed a large reduction in severe retinopathy (RR 0.19; CI 0.07, 0.50).[1,21] There

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

have not been other randomized controlled trials of different oxygen targeting starting soon after birth to reduce retinopathy. However, results of most non-randomized studies show that lower oxygen saturation targeting reduces retinopathy of prematurity. The current trial confirmed that lower oxygen targeting results in a large reduction of severe retinopathy.

In summary, lower oxygen saturation targeting did not affect the combined outcome of threshold retinopathy/death but increased mortality and decreased threshold retinopathy. There are several ongoing trials across the world that address the same intervention tested in the current trial as well as a planned prospective meta-analysis.[22] These trials use the same algorithms for oxygen saturation targeting so their data will be easy to combine in a meta-analysis to determine short and long term effects of oxygen saturation targeting. At the present time, it is important that these trials continue and that the investigators and the data safety and monitoring committees of these trials are aware of the results of the current trial so that appropriate decisions can be made regarding their interim analyses, completion of the trials, and dissemination of the data. The current trial raises the concern of adverse hospital outcomes due to oxygen saturation targeting in the 85 to 89% range. Neurodevelopmental assessments are being performed at 18-22 months corrected age. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years but at the present time, caution should be exercised regarding oxygen targeting in the low range for extremely premature babies, such as those tested in the current trial.

Here is the document; I only made some cosmetic changes to the one I sent to you earlier. So, Kris is going to initiate the process of establishing preliminary contact with these chairs.

Since we are sending this on behalf of NICHD, would you like to draft a short accompanying message?

Thanks

Abhik

Selected Information from The Fourth Data Safety and Monitoring Committee Report for The SUrfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants (SUPPORT Trial)

November 4, 2009

Prepared by the NICHD Neonatal Research Network Data Center at RTI International, Research Triangle Park, NC

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

A. Methods and Procedures

Study Design

The SUrfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants (SUPPORT Trial) is a prospective, randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (NRN). The individual factors to be tested are:

1) A prospective comparison of CPAP and a permissive ventilatory strategy begun in the delivery room and continuing in the NICU with early ($\leq$ 1 hour) surfactant and mechanical ventilation.

2) A prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant no longer requires ventilatory support or oxygen.

The oxygen saturation monitoring portion of the study is designed to allow a blinded comparison of 2 different SpO2 levels using specially designed pulse oximeters that are calibrated to provide actual SpO2 values when the SpO2 is < 85% and > 95%. This methodology provides clinicians and caretakers with the infants' actual SpO2 values during hypoxia and hyperoxia, within the current parameters of clinically accepted practice.

Primary Hypotheses

1) Relative to infants managed with prophylactic/early surfactant and conventional ventilation, the use of early CPAP and a permissive ventilatory strategy in infants of less than 28 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks postmenstrual age (PMA).

2) Relative to infants managed with a higher SpO2 range, the use of a lower SpO2 range (85% to 89%) will result in an increase in survival without the occurrence of threshold ROP and/or the need for surgical intervention.

Secondary Hypotheses

Use of continuous positive airway pressure (CPAP) with a permissive ventilator strategy and/or a lower SpO2 range starting at birth in the delivery room will result in the following:

- A decrease in mortality or neurodevelopmental impairment (NDI) at 18-22 months corrected age
- A decreased frequency of endotracheal intubation before 10 minutes of age
- A decreased incidence of surfactant treatment
- A decreased incidence of air leaks on admission and overall
- A decreased duration of intubation
- A decreased duration of mechanical ventilation
- A decreased duration of oxygen supplementation
- A decreased duration of the percentage of pulse oximetry values > 90%
- A decrease in the percentage of infants who receive postnatal steroids for BPD
- A decreased incidence of BPD at 36 weeks PMA
- A decreased incidence of threshold ROP and/or the need for surgical intervention
- A decreased incidence of necrotizing enterocolitis (NEC)
- A decreased incidence of intraventricular hemorrhage (IVH) and severe IVH
- A decreased incidence of periventricular leukomalacia (PVL)
- A decreased incidence of NDI at 18-22 month follow-up
- A decreased incidence of cerebral palsy at 18-22 month follow-up
- A decreased incidence of blindness of at least one eye at 18-22 month follow-up

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Study Population

Study subjects are infants of 24 0/7 to 27 6/7 weeks gestational age (GA) at birth for which a decision has been made to provide full resuscitation as required. Infants 27 weeks or less gestation (completed weeks by best obstetric estimate) are enrolled because over 80% of such infants in the Network are intubated, usually early in their neonatal course. There are 2 randomization strata, infants of 24 0/7 to 25 6/7 weeks GA, and infants of 26 0/7-27 6/7 weeks GA by best obstetrical estimate. The purpose of stratification is to assure an appropriate distribution of risk among the four study arms. The study is not powered to detect outcome differences between strata.

Inclusion Criteria

- Infants with a minimal gestational age of 24 weeks 0 days to 27 completed weeks (up to 27 6/7ths) by best obstetrical estimate
- Infants who will receive full resuscitation as necessary, i.e., no parental request or physician decision to forego resuscitation
- Infants whose parents/legal guardians have provided consent for enrollment, or
- Infants without known major congenital malformations

Exclusion Criteria

- Any infant transported to the center after delivery
- Infants whose parents/legal guardians refuse consent
- Infants born during a time when the research apparatus/study personnel are not available
- Infants < 24 weeks 0 days or $\geq$ 28 weeks 0 days, completed weeks of gestation

Sampling Recruitment and Screening Procedures

Infants are recruited for this study by approaching parent(s) at the time of hospital admission when there is a perceived risk of premature delivery at 27 6/7ths weeks or less.

Sample Size

The required sample size for this trial was determined to be 1,310 to ensure 80% power for detecting an absolute difference of 10% in the two primary outcomes and the NDI secondary outcome. These results were based on observed prevalence of these outcomes in the Network Generic Data Base (GDB, a registry of all <1500 g births in the Network), and corrected for two primary outcomes (assumed significance level of 2%), for a clustering effect because of multiples being randomized to the same treatment, as well as for attrition. Note that this sample size is not sufficient to permit detection of interaction effects between the two treatments with reasonable power.

Randomization

Randomization is stratified by study site and gestational age group, occurs prior to delivery for consented deliveries, and is performed by utilizing specially prepared double-sealed envelopes. Deliveries are randomized as a unit, thus multiples, twins, triplets etc are randomized to the same arm of the trial. Appropriate sample size adjustments have been made to account for this clustering effect.

Study Intervention

The intervention begins after birth when the infant is given to the resuscitation team. The conduct of the resuscitation follows usual guidelines, and once stabilized, all Control infants in the Ventilation arm receive prophylactic/early surfactant (within 1 hour of age) whereas all

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Treatment infants are placed on CPAP/PEEP following stabilization and intubated only for resuscitation indications.

The assignment to either a high or low SpO2 by study oximeter assignment is performed immediately following NICU admission, with a maximum allowable delay of 2 hours following NICU admission. There are two ranges of SpO2 utilized during this trial. The Low target range is 85% to 89% and the High target range is 91% to 95%. The altered Pulse Oximeters (PO) display a range of 88% to 92% when the SpO2 ranges are in the Target ranges indicated above. Thus a Low range PO reads 88% when the actual SpO2 is approximately 86%, and 92% when the actual SpO2 is 89%. Similarly the High range PO displays 88% when the actual SpO2 is 91% and indicates 92% when the actual SpO2 is approximately 95%.

Interim Monitoring Plan

The Data Safety Monitoring Committee will review the progress of the study with respect to efficacy and adverse events in a sequential fashion using interim monitoring boundaries. Efficacy is measured at approximately 25%, 50%, 75%, and 100% of outcome assessment. Primary outcomes are analyzed at these time points by statistically adjusting for familial clustering and stratification by gestational age stratum and center. To control for the inflation of Type I error associated with sequential testing, O'Brien-Fleming[1] boundaries are calculated using a Lan-DeMets[2] spending function. Safety is monitored at these time points as well using Pocock[3] boundaries for adverse event monitoring.

B. Selected Results

Enrollment

This is an extract from the report prepared for the final planned DSMC look at 100% of the primary outcome data for the SUPPORT Trial. As of February 2009, 1,316 infants have been enrolled in SUPPORT, exceeding the total expected enrollment of 1,310.

Treatment Compliance in Oxygen Saturation Arm

In the oxygen saturation arm, target saturation ranges are 85-89% and 91-95% for the Low and High SpO2 arms, respectively. **Table I** shows the percent of time infants on supplemental oxygen spent in various SpO2 ranges. Supplemental oxygen is defined as FiO2>.21 during the first 14 days of life (FiO2 is reported every two hours) or as documented oxygen use from day of life 15 through 36 weeks (oxygen use is recorded every 6 hours).

Time on supplemental oxygen	Oxygen saturation arm	Percent in narrow target 88-92 (Display)	Percent <84	Percent 84-96	Percent >96
Days of life 1-14	Low SpO2	19.7	11.8	76.2	12.0
	High SpO2	49.3	6.3	79.5	14.2
Day 15 to 36 wks	Low SpO2	15.5	15.4	67.1	17.6
	High SpO2	37.0	10.5	67.7	21.8

Table I Distribution of Time in SpO2 Display Ranges while on Supplemental Oxygen

Separation in Oxygen Saturation Arm **Table II** and **Figure I** address treatment separation in the Oxygen Saturation arm of the SUPPORT Trial. **Table II** shows the amount of time infants in

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

each treatment group spend in room air. Only data from March 2006 to the present are included in Table 3.b, because since that time supplemental oxygen use has been recorded every two hours for day of life (DOL) 1-14 and every 6 hours thereafter. These data indicate some separation between the two treatment groups.

	DOL 1-14		DOL 15+	
	High SpO2	Low SpO2	High SpO2	Low SpO2
Hours in room air (hours in thousands)	35% (57/162)	46% (71/157)	35% (213/600)	46% (254/552)

Table II Percent of Time Spent in Room Air Since March 2006, by Treatment and Day of Life

Figure I shows the distribution of SpO2 values during time spent on supplemental oxygen for infants in the Low and High SpO2 target groups through 36 weeks PMA. There is modest separation between the groups, along with substantial overlap. The area under the overlapping portions of the curves is 85%. Thus, 15% of the area under each curve does not overlap the other.

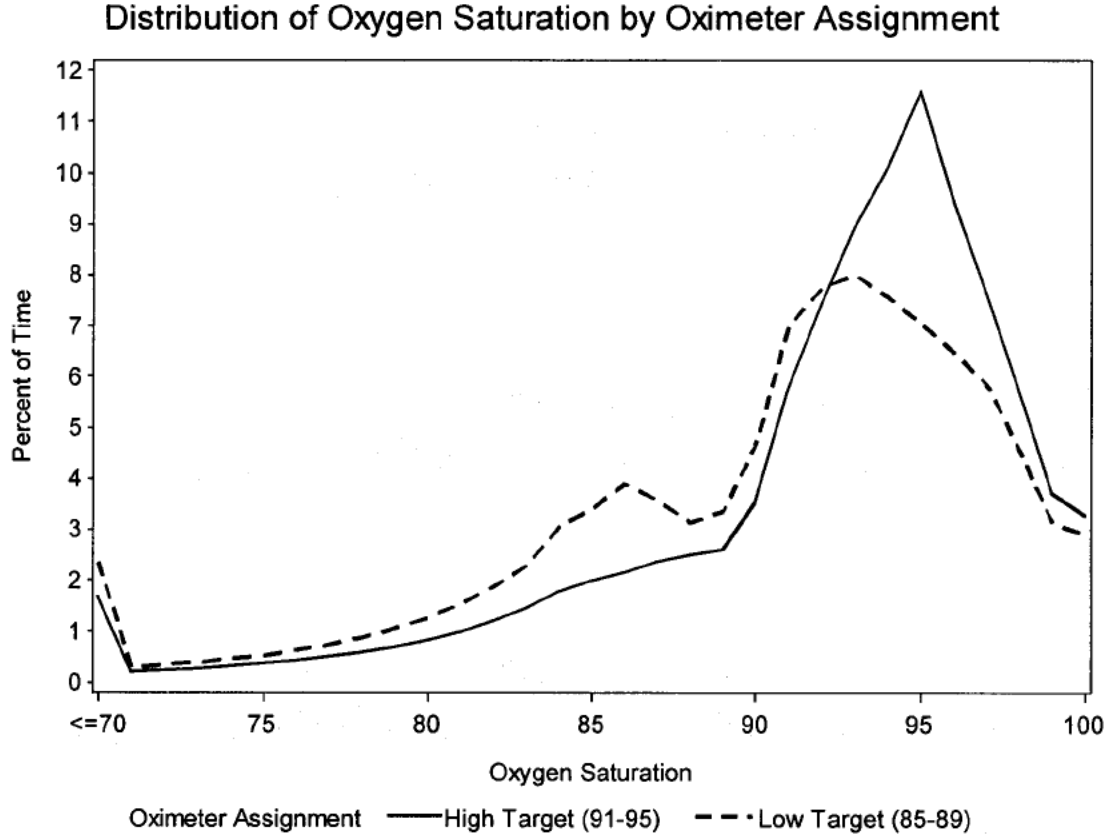

Figure I Percent of Time Spent at Each SpO2 Value for Infants in Low and High Target Groups (Includes only time on supplemental oxygen through 36 weeks PMA)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Mortality Information

Table III show the percent of infants in each treatment group who died during the course of the SUPPORT Trial. The table also displays adjusted p-values for statistical tests comparing the percent of infants who died in each level of the two treatment factors. The tests are adjusted for familial clustering due to multiple births and for stratification by center and gestational age group. There is a statistically significant difference in the death rate between treatments in the oxygen saturation arm, with higher mortality in the low SpO2 arm.

Outcome	Oxygen Saturation Arm		Adjusted P-value
	Low SpO2 (N=654)	Low SpO2 (N=654)	
Death	20% (130/654)	16% (107/662)	0.0412

Table III Death in the Oxygen Saturation Arm

Gestational age was a significant predictor of death in the tests presented in Table III ($p<0.0001$). **Table IV** presents the mortality information by gestational age stratum. Note that the 26-27 week gestational age stratum includes three infants born at 28 weeks gestational age.

Gestational Age Strata	Oxygen Saturation Arm		Adjusted P-value
	Low SpO2	High SpO2	
GA 24-25 weeks (N=565)	31% (85/276)	25% (73/289)	0.1225
GA 26-27 weeks (N=751)	12% (45/378)	9% (34/373)	0.1811

Table IV Death in the Oxygen Saturation Arm by Gestational Age Group

Cause of Death **Table V** lists causes of death by treatment and gestational age group to address safety concerns regarding RDS and other factors contributing to mortality.

Cause of Death	Low SpO2		High SpO2	
	24-25 wks (N=85)	26-27 wks (N=45)	24-25 wks (N=73)	26-27 wks (N=34)
RDS	27% (23/85)	18% (8/45)	29% (21/73)	29% (10/34)
BPD	9% (8/85)	13% (6/45)	12% (9/73)	3% (1/34)
Infection	19% (16/85)	20% (9/45)	18% (13/73)	24% (8/34)
NEC	20% (17/85)	13% (6/45)	12% (9/73)	15% (5/34)
CNS Insult	12% (10/85)	4% (2/45)	8% (6/73)	9% (3/34)
Immaturity	6% (5/85)	4% (2/45)	4% (3/73)	0% (0/34)
Other	7% (6/85)	27% (12/45)	16% (12/73)	21% (7/34)

Stephanie
I looked at the boilerplate in detail for Wally's paper.
I will repoll the steering committee regarding CTSA support and this will need to be accurately updated.
SWA: I'll make any changes once all votes are in. Still missing info from Case and Emory. I took out Indiana's and Utah's per PI responses. Have kept in Yale's, Stanford's, and Iowa's.

Emory has indicated an alternate author.
SWA: Changed

For individual site grant numbers, please list the U10 awards first (they funded the vast majority of study costs, the GCRCs and CTSA funding was much less).
SWA: Done

Please affirm/check the following items:
Mickey's institution name - I believe this is North Shore, but check with him or his staff. Also his tenure for the NRN should be 2006-present in stead of 2011.
SWA: No change, per Mickey.

Did indiana indicate that
Faithe Hamer had a role (in addition to FU)?
SWA: Sent Leslie a question about this.

RTI listing should also include Dennis Wallace, PhD.
SWA: Done

Does UCSD need to include Rene Bridges? She responded to several of the queries I sent over time.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

SWA: Done, per Wade Rich.

Does Iowa need to list Gretchen - one of the other research nurses?
SWA: Ed does NOT believe she should be included.

University of New Mexico - Conra Lacy is not listed, yet she is the lead coordinator. -please check.
SWA: Done, per Kristi.

UT southwestern - Diana Vasil is not listed and has also been involved with query resolution.
SWA: Sent Pablo a question about this.

The DSMC is missing and needs to be listed.
SWA: Done

We should also list the NHLBI folks. I will get a list of them.
SWA: Waiting to hear back from NHLBI.

Ask the houston site if any recruitment occured at LBJ hospital.
SWA: LBJ did NOT participate, per Georgia.

Let me know if you need help getting responses. This is a pivotal trial and I want to get it right.

Thanks so much for putting this together.

Rose

Dear Rose, Neil, Marie and Abhik:

Enclosed is the next draft. I have received comments from some of you and from Michele, and I have responded to the issues raised.

I talked with Abhik and he agreed Marie should get a Kaplan Meier plot for mortality (New Fig 2).

I think it is ready to be sent to the rest of the Subcommittee.

RTI INTERNATIONAL | **Memorandum**

November 4, 2009

SUPPORT Trial Final DSMC Review

TO: SUPPORT PI (co-PI)
NICHD

FROM: The Data Coordinating Center

SUBJECT: Final DSMC Protocol Review

The NICHD NRN DSMC met on November 4, 2009 in Rockville, MD to discuss the final planned interim analyses the *SUrfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants (The SUPPORT Trial).* Their recommendations and comments are below:

1. The DSMC agreed it was our obligation to share stratified mortality data from the oxygen saturation arm of the SUPPORT trial with DSMCs monitoring the safety data for other similarly conducted international trials without waiting for the primary papers to be published, so that those DSMCs can interpret the data. Additionally, we should share the oxygen saturation separation data so that the results can be put in context.
2. The DSMC requested additional information about the total number of protocol deviations and the total number of infants that had deviations.
3. The DSMC requested a 2x2 factorial distribution of mortality (death by cohort) and detailed reasons of death for those infants listed in the 'other' death category.
4. The DSMC requested that the DCC statistically test whether the separation in the saturation arms is statistically significant.
5. The DSMC has requested an additional review of the complete 18-22 month Follow Up data when available.

Selected Information from

The Fourth Data Safety and Monitoring Committee Report for The SUrfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants (SUPPORT Trial)

CONFIDENTIAL

November 4, 2009

Prepared by the NICHD Neonatal Research Network Data Center at RTI International, Research Triangle Park, NC

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

A. Methods and Procedures

Study Design

The SUrfactant Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants (SUPPORT Trial) is a prospective, randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network. The individual factors to be tested are:

1) A prospective comparison of CPAP and a permissive ventilatory strategy begun in the delivery room and continuing in the NICU with early ($\leq$ 1 hour) surfactant and mechanical ventilation.

2) A prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant no longer requires ventilatory support or oxygen.

The oxygen saturation monitoring portion of the study is designed to allow a blinded comparison of 2 different SpO2 levels using specially designed pulse oximeters that are calibrated to provide actual SpO2 values when the SpO2 is < 85% and > 95%. This methodology provides clinicians and caretakers with the infants' actual SpO2 values during hypoxia and hyperoxia, within the current parameters of clinically accepted practice.

Primary Hypotheses

1) Relative to infants managed with prophylactic/early surfactant and conventional ventilation, the use of early CPAP and a permissive ventilatory strategy in infants of less than 28 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks postmenstrual age (PMA).

2) Relative to infants managed with a higher SpO2 range, the use of a lower SpO2 range (85% to 89%) will result in an increase in survival without the occurrence of threshold ROP and/or the need for surgical intervention.

Secondary Hypotheses

Use of continuous positive airway pressure (CPAP) with a permissive ventilator strategy and/or a lower SpO2 range starting at birth in the delivery room will result in the following:

- A decrease in mortality or neurodevelopmental impairment (NDI) at 18-22 months corrected age
- A decreased frequency of endotracheal intubation before 10 minutes of age
- A decreased incidence of surfactant treatment
- A decreased incidence of air leaks on admission and overall
- A decreased duration of intubation
- A decreased duration of mechanical ventilation
- A decreased duration of oxygen supplementation
- A decreased duration of the percentage of pulse oximetry values > 90%
- A decrease in the percentage of infants who receive postnatal steroids for BPD
- A decreased incidence of BPD at 36 weeks PMA
- A decreased incidence of threshold ROP and/or the need for surgical intervention
- A decreased incidence of necrotizing enterocolitis (NEC)
- A decreased incidence of intraventricular hemorrhage (IVH) and severe IVH
- A decreased incidence of periventricular leukomalacia (PVL)
- A decreased incidence of NDI at 18-22 month follow-up
- A decreased incidence of cerebral palsy at 18-22 month follow-up
- A decreased incidence of blindness of at least one eye at 18-22 month follow-up

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Study Population

Study subjects are infants of 24 0/7 to 27 6/7 weeks gestational age (GA) at birth for which a decision has been made to provide full resuscitation as required. Infants 27 weeks or less gestation (completed weeks by best obstetric estimate) are enrolled because over 80% of such infants in the Network are intubated, usually early in their neonatal course. There are 2 randomization strata, infants of 24 0/7 to 25 6/7 weeks GA, and infants of 26 0/7-27 6/7 weeks GA by best obstetrical estimate. The purpose of stratification is to assure an appropriate distribution of risk among the four study arms. The study is not powered to detect outcome differences between strata.

Inclusion Criteria

- Infants with a minimal gestational age of 24 weeks 0 days to 27 completed weeks (up to 27 6/7ths) by best obstetrical estimate
- Infants who will receive full resuscitation as necessary, i.e., no parental request or physician decision to forego resuscitation
- Infants whose parents/legal guardians have provided consent for enrollment, or
- Infants without known major congenital malformations

Exclusion Criteria

- Any infant transported to the center after delivery
- Infants whose parents/legal guardians refuse consent
- Infants born during a time when the research apparatus/study personnel are not available
- Infants < 24 weeks 0 days or $\geq$ 28 weeks 0 days, completed weeks of gestation

Sampling Recruitment and Screening Procedures

Infants are recruited for this study by approaching parent(s) at the time of hospital admission when there is a perceived risk of premature delivery at 27 6/7ths weeks or less.

Sample Size

The required sample size for this trial was determined to be 1,310 to ensure 80% power for detecting an absolute difference of 10% in the two primary outcomes and the NDI secondary outcome. These results were based on observed prevalence of these outcomes in the Network Generic Data Base (GDB, a registry of all <1500 g births in the Network), and corrected for two primary outcomes (assumed significance level of 2%), for a clustering effect because of multiples being randomized to the same treatment, as well as for attrition. Note that this sample size is not sufficient to permit detection of interaction effects between the two treatments with reasonable power.

Randomization

Randomization is stratified by study site and gestational age group, occurs prior to delivery for consented deliveries, and is performed by utilizing specially prepared double-sealed envelopes. Deliveries are randomized as a unit, thus multiples, twins, triplets etc are randomized to the same arm of the trial. Appropriate sample size adjustments have been made to account for this clustering effect.

Study Intervention

The intervention begins after birth when the infant is given to the resuscitation team. The conduct of the resuscitation follows usual guidelines, and once stabilized, all Control infants in the Ventilation arm receive prophylactic/early surfactant (within 1 hour of age) whereas all

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Treatment infants are placed on CPAP/PEEP following stabilization and intubated only for resuscitation indications.

The assignment to either a high or low SpO2 by study oximeter assignment is performed immediately following NICU admission, with a maximum allowable delay of 2 hours following NICU admission. There are two ranges of SpO2 utilized during this trial. The Low target range is 85% to 89% and the High target range is 91% to 95%. The altered Pulse Oximeters (PO) display a range of 88% to 92% when the SpO2 ranges are in the Target ranges indicated above. Thus a Low range PO reads 88% when the actual SpO2 is approximately 86%, and 92% when the actual SpO2 is 89%. Similarly the High range PO displays 88% when the actual SpO2 is 91% and indicates 92% when the actual SpO2 is approximately 95%.

Interim Monitoring Plan

The Data Safety Monitoring Committee will review the progress of the study with respect to efficacy and adverse events in a sequential fashion using interim monitoring boundaries. Efficacy is measured at approximately 25%, 50%, 75%, and 100% of outcome assessment. Primary outcomes are analyzed at these time points by statistically adjusting for familial clustering and stratification by gestational age stratum and center. To control for the inflation of Type I error associated with sequential testing, O'Brien-Fleming[1] boundaries are calculated using a Lan-DeMets[2] spending function. Safety is monitored at these time points as well using Pocock[3] boundaries for adverse event monitoring.

B. Results

Enrollment

This is the final planned DSMC look at 100% of the primary outcome data for the SUPPORT Trial. As of February 2009, 1,316 infants have been enrolled in SUPPORT, exceeding the total expected enrollment of 1,310.

~~**Table 1.a** displays information related to enrollment.~~

Category		Number	Percent
~~Screened*~~		~~3547~~	~~100%~~
~~Eligible~~		~~3186~~	~~90%~~
~~Consented~~		~~1384~~	~~39%~~

	High SpO2	49.3	6.3	79.5	14.2
Day 15 to 36 wks	Low SpO2	15.5	15.4	67.1	17.6
	High SpO2	37.0	10.5	67.7	21.8

Table 3.a~~l~~ Distribution of Time in SpO2 Display Ranges while on Supplemental Oxygen

Separation in Oxygen Saturation Arm **Table 3.b~~ll~~** and **Figure ~~1~~** address treatment separation in the Oxygen Saturation arm of the SUPPORT Trial. **Table 3.b~~ll~~** shows the amount of time infants in each treatment group spend in room air. Only data from March 2006 to the present are included in Table 3.b, because since that time supplemental oxygen use has been recorded every two hours for day of life (DOL) 1-14 and every 6 hours thereafter. These data indicate some separation between the two treatment groups.

Formatted: Font: Bold

Formatted: Font: Bold

	DOL 1-14		DOL 15+	
	High SpO2	Low SpO2	High SpO2	Low SpO2
Hours in room air (hours in thousands)	35% (57/162)	46% (71/157)	35% (213/600)	46% (254/552)

Table 3.b~~ll~~ Percent of Time Spent in Room Air Since March 2006, by Treatment and Day of Life

Figure ~~1~~ shows the distribution of SpO2 values during time spent on supplemental oxygen for infants in the Low and High SpO2 target groups through 36 weeks PMA. There is modest separation between the groups, along with substantial overlap. The area under the overlapping portions of the curves is 85%. Thus, 15% of the area under each curve does not overlap the other.

Primary Outcomes

Tables 4.a and **4.b** compare the two primary outcomes for the ventilation and oxygen saturation arms. All enrolled infants had a known outcome for survival without BPD at 36 weeks, while 1,221 infants had a known outcome for survival without severe ROP (93% of total enrollment). P-values for testing for treatment differences are adjusted for familial clustering and for stratification by gestational age group and center.

[illegible]	[illegible] (N=663)	[illegible] (N=653)	Adjusted p-value
Survival without BPD (Physiologic Definition) at 36 weeks	52% (346/663)	49% (320/653)	0.33423039
Survival without BPD (Supplemental Oxygen) at 36 weeks	51% (3401/663)	46% (300/653)	0.06990719
Survival without severe ROP	72% (444/620)	68% (408/601)	0.12100971

Table 4.a Primary Outcomes for Ventilation Arm

Primary Outcome	[illegible] (N=654)	[illegible] (N=662)	Adjusted p-value
Survival without BPD (Physiologic Definition) at 36 weeks	51% (335/654)	50% (331/662)	0.94328988
Survival without BPD (Supplemental Oxygen) at 36 weeks	52% (3378/654)	46% (303/662)	0.07200754
Survival without severe ROP	72% (434/605)	68% (418/616)	0.19172050

Table 4.b Primary Outcomes for Oxygen Saturation Arm

Secondary Outcomes

Table 5.a shows selected secondary outcomes, by treatment. Tests between treatment groups were adjusted for stratification by center and gestational age and for familial clustering. Percentages and means (± standard error) for which there is a significant difference between treatments (adjusted p<0.05) are bolded. Aside from certain expected differences because of the nature of the interventions, the ventilation arm has suggestive trends in favor of CPAP for postnatal steroids for BPD (adjusted p=0.0005), and in favor of Surfactant for pneumothoraces and any grade of IVH (adjusted p-values of 0.0786 and 0.0265, respectively). Aside from expected differences due to treatments in the oxygen saturation arm, there were trends in favor of Low SpO2 for BPD by the supplemental oxygen definition (adjusted p=0.00170020), severe ROP in one or both eyes (adjusted p=0.0001), and days on supplemental oxygen (adjusted p=0.0002) among survivors.

At the 18 month follow-up visit, there was a trend in favor of Surfactant for NDI among survivors (adjusted p-value=0.0554). However, neither the ventilation nor oxygen saturation arm showed a significant difference between groups for the composite outcome of NDI or death.

Table 5.a Secondary Outcomes, by Treatment

*Air leaks collected since 10/15/07 include PIE and pneumopericardium in addition to pneumothorax

Tables 5.b, 5.c and 5.d address safety-related questions pertaining to IVH and air leaks. **Table 5.b** shows the frequency of air leaks in the first 14 days of life (data collected since October 15, 2007, include PIE and pneumopericardium in addition to pneumothorax) and IVH in the SUPPORT Trial. There is some evidence of an association, with any IVH and severe IVH (grades III-IV) occurring more frequently in cases of air leak (unadjusted chi-square p-values both<0.0001). **Table 5.c** shows the relationship between pneumothorax and IVH. Unadjusted chi-square p-values for the independence of pneumothorax and any IVH or severe IVH were both <0.0001. **Table 5.d** shows the distribution of the number of hours between delivery and surfactant receipt for infants with and without pneumothorax.

Category	N	Mean ± StdDev	25th Percentile	Median	75th Percentile	90 Percentile
Pneumothorax = Yes	88	7.4 ± 14.9	0.4	0.7	8.9	24.1
Pneumothorax = No	995	3.0 ± 9.1	0.3	0.6	1.3	5.7

Table 5.d Number of Hours Between Birth and Receipt of Surfactant

Note: 231 infants without pneumothorax and 2 with pneumothorax are not included in this table because the infant did not receive surfactant or timing of surfactant was unknown

Death and other Adverse Events Mortality Information

Deaths **Tables 6.a** and **6.bIII** show the percent of infants in each treatment group who died during the course of the SUPPORT Trial. The table also displays adjusted p-values for statistical tests comparing the percent of infants who died in each level of the two treatment factors. The tests are adjusted for familial clustering due to multiple births and for stratification by center and gestational age group. There is a statistically significant difference in the death rate between treatments in the oxygen saturation arm, with higher mortality in the low SpO2 arm.

Outcome	Ventilation Arm		Adjusted P-value
Death	16% (109/663)	20% (128/653)	0.1259

Table 6.a Death in the Ventilation Arm

Outcome	Oxygen Saturation Arm		Adjusted P-value
	Low SpO2 (N=654)	High SpO2 (N=654)	
Death	20% (130/654)	16% (107/662)	0.0412

Table 6.bIII Death in the Oxygen Saturation Arm

Gestational age was a significant predictor of death in the tests presented in Table 6.a and 6.bIII ($p<0.0001$). **Tables 6.c** and **6.dIV** presents the mortality information by gestational age stratum. Note that the 26-27 week gestational age stratum includes three infants born at 28 weeks gestational age. There is a significant difference in deaths between the CPAP and Surfactant groups for infants in the 24-25 week gestational age stratum.

Table V Cause of Death, by Oxygen Saturation Treatment and GA at Birth

~~All Adverse Events Adverse events (AEs) in the first 14 days of life are recorded on a designated SUPPORT form. Later events are identified using other SUPPORT and Generic Database (GDB) forms. AEs monitored for the SUPPORT Trial in addition to death include:~~

- ~~Air leak (data collected since October 15, 2007, include PIE and pneumopericardium in addition to pneumothorax)~~
- ~~Need for chest compressions or epinephrine in the delivery room or NICU~~
- ~~Severe IVH (Grades 3-4, Papile)~~
- ~~Pulmonary hemorrhage~~
- ~~Nasal breakdown requiring discontinuation of nasal prongs~~

Table 6.f Cause of Death, by Oxygen Saturation Treatment and GA at Birth

Table 6.g shows the overall percent of infants in each treatment group who had an AE, as well as the number of infants who experienced each individual type of event. There was not a significant difference between treatment groups in the overall percent of infants who had an AE in either the ventilation or oxygen saturation arm (p-values 0.9393 and 0.0726, respectively, adjusted for familial clustering due to multiple births and for stratification by center and gestational age group). Neither arm of the study had a significant difference between treatment groups in the overall percent of infants who had an AE when viewed by GA group.

The only individual events showing a trend for differences between treatments in adjusted tests were nasal breakdown (ventilation arm p-value 0.0896) and, as seen earlier, death in the oxygen saturation arm (p-value=0.0412).

Characteristic	Ventilation Arm		Oxygen Saturation Arm	
	CPAP (N=663)	Surfactant (N=653)	Low SpO2 (N=654)	High SpO2 (N=662)
Air leak in the first 14 days	7% (45/663)	7% (48/653)	8% (51/654)	6% (42/662)
Chest compressions/drugs in DR	5% (36/660)	7% (46/653)	6% (41/651)	6% (41/662)
IVH grade 3 or 4	14% (92/642)	11% (72/628)	13% (83/630)	13% (81/640)

Characteristic	Ventilation Arm		Oxygen Saturation Arm	
	CPAP/NIPPV (N=663)	Ventilation (N=653)	Low SpO2 (N=654)	High SpO2 (N=662)
Pulmonary hemorrhage	5% (33/654)	7% (45/636)	7% (44/641)	5% (34/649)
Nasal breakdown in first 14 days	3% (17/663)	1% (8/653)	2% (14/654)	2% (11/662)
Death	16% (109/663)	20% (128/653)	20% (130/654)	16% (107/662)
Other AE in first 14 days	5% (33/663)	5% (33/653)	5% (33/654)	5% (33/662)
All adverse events combined	37% (247/663)	37% (239/653)	39% (255/654)	35% (231/662)

Table 6.g Adverse Events by Treatment Arm

Historic AE Rates in the Neonatal Research Network - In order to provide comparable prevalence rates for the AEs experienced by this severely ill population, **Table 6.h** displays rates of AEs among infants born at Neonatal Research Network (NRN) centers between 2002 and 2004. The table shows the percent of infants experiencing AEs for all centers combined, as well as ranges across the individual centers. Death and overall AE rates in the SUPPORT Trial appear to be comparable to, and fall within the plausible ranges of such events in the NRN population.

Adverse Event	22 to 28 Weeks Gestational Age		23 to 27 Weeks Gestational Age		All Infants 22 to 27 Weeks Gestational Age	
	Percent	Range	Percent	Range	Percent	Range
Air leak (pneumothorax)	11.0	2.9 - 20.6	6.1	1.1 - 13.0	8.2	1.9 - 16.1
Chest compressions/ epinephrine in the DR	13.9	2.8 - 42.1	9.1	3.2 - 23.2	11.2	3.2 - 31.8
Severe IVH (grades III-IV)	24.2	14.0 - 38.9	11.7	2.3 - 20.8	16.9	8.4 - 26.4
Pulmonary hemorrhage	12.3	2.5 - 32.0	6.5	1.1 - 26.9	9.0	3.4 - 29.3
Death	35.5	19.9 - 66.1	13.3	4.4 - 26.8	23.1	12.1 - 46.4
Any AE listed above	57.4	42.0 - 78.6	31.5	20.8 - 53.6	42.9	23.3 - 66.1

Table 6.h Adverse Event Rates in the NRN: Births in 2002-2004

Necrotizing Enterocolitis (NEC) and Patent Ductus Arteriosus (PDA) - In December 2007, a Hot Topics presentation regarding oxygen saturation prompted concern that NEC and/or PDA rates might increase when infants were maintained in certain saturation ranges. Thus, monitoring for those two adverse events was added to the safety monitoring routine for SUPPORT.

Table 6.i and shows the percent of infants in the two treatment groups of the oxygen saturation arm who had NEC or PDA, as well as p-values for statistical tests comparing the percent of infants experiencing those events in the two treatment groups. The tests are adjusted for familial clustering due to multiple births and for stratification by center and gestational age group.

Outcome	Oxygen Saturation Arm		Adjusted p-value
	Low SpO2 (N=654)	High SpO2 (N=662)	
NEC	12% (76/641)	11% (70/649)	0.5076

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

PDA	48% (307/641)	50% (324/648)	0.4320

Table 6.i Tests for Differences Between Treatments in the Oxygen Saturation Arm

NEC and PDA Rates in the Generic Database **Table 6.j** displays rates of NEC and PDA among infants born at Neonatal Research Network (NRN) centers between 2002 and 2004. The table shows the percent of infants with NEC and PDA for all centers combined, as well as ranges across the individual centers. The overall rates of NEC and PDA in the SUPPORT Trial are comparable to the historic GDB rate.

NEC	12.3	5.0 – 25.9	9.7	3.9 – 19.4	10.8	5.1 – 22.3
PDA	57.1	37.8 – 75.3	44.1	18.2 – 68.9	49.7	28.1 – 71.7

Table 6.j NEC and PDA Rates in the NRN: Births in 2002-2004

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Protocol Deviations

Table 7 summarizes protocol deviations for all enrolled infants. A total of 388 protocol deviations were reported by the centers or identified using study forms. Most of these were related to failure to administer surfactant in the first hour if required by protocol (infants in the CPAP arm are required to receive surfactant if intubated for resuscitation) or failure to use study oximeter at times required by protocol. Note that in 70% of the cases where surfactant was not given in the first hour it was still administered within two hours of delivery, and in 94% of cases it was administered within 3 hours of birth. Except for certain expected differences due the nature of the interventions, the distribution of the deviations does not appear substantially skewed between the two groups in either arm.

	Initial Therapy		Oxygen Saturation Arm	
	CPAP	Surfactant	Low Sat	High Sat
CPAP not initiated if required by protocol	5	1	2	4
Surfactant not given in the first hour (if required by protocol)	45	36	43	38
Oximeter not started within two hours of NICU admission	15	16	13	18
Infant received incorrect treatment	15	11	15	11
Failure to use study oximeter at times required by protocol	55	57	57	55
Non-study oximeter used at same time as study oximeter	8	7	9	6
Mechanical ventilation initiated for other than study criteria	2	0	1	1
NSIMV initiated in infant not previously intubated	10	0	3	7
Extubation (excluding unplanned) for other than study criteria	2	10	8	4
Failure to extubate infant if all criteria met	8	4	6	6
Infant intubated without meeting study criteria	2	0	1	1
Infant received postnatal steroids in first 21 days of life	15	19	20	14
Randomization/consent errors	14	18	15	17
Other	6	7	5	8
Total	**202**	**186**	**198**	**190**

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven minimal ventilator strategy. Infants randomized to surfactant were intubated and received surfactant within 60 min minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while in the NICU and receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was 49% in the CPAP group versus 54% in the surfactant group, (RR 0.91, 95% CI 0.82, 1.00, p=0.06 when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.019) and fewer required intubation or post natal steroids for BPD, ~~(p<.001)~~ (p<0.001).

Conclusions: The use of CPAP in such infants is an effective evidence based alternative to intubation and surfactant.

Introduction:

At the present time, there is no agreement as to the optimal approach to respiratory support for the extremely low birth weight (ELBW) infant following delivery. Positive End Expiratory Pressure (PEEP) has been shown to be of benefit in maintaining functional residual capacity (FRC), and continuous positive airway pressure appears beneficial during cardiopulmonary resuscitation[1]. Gregory et al in 1971 first demonstrated that the use of CPAP started at approximately 5.9 hours (+12.4hrs) for their infants < 1500 gm at birth, improved oxygenation[2] in newborn infants with respiratory distress; these observations were followed by prospective studies that demonstrated improved survival in premature infants treated with early CPAP[3]. A review of prospective studies evaluating early (not delivery room) CPAP in the pre-surfactant, pre-antenatal steroid era found that early CPAP improved survival overall and for infants greater than 1500 gm, and was associated with increased pneumothoraces.[4] A more recent review of prophylactic CPAP started in the delivery room reviewed only 2 available trials and found no significant difference between the CPAP and conventionally managed infants and noted a trend to increased adverse outcomes for the CPAP treated infants.[5]

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

There is substantial retrospective evidence suggesting a benefit for early CPAP in experiences from both the US and other countries.[678] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following the initiation of early CPAP treatment.[91011]

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[1213] The surfactant trials preceeded widespread use of antenatal corticosteroids to promote lung maturation. Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI). [14]

The recent COIN trial randomized 610 infants from 25 weeks 0 days to 28 weeks 6 days gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[15] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analyses~~6~~, and a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with no difference in death or BPD at 36 weeks.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

In view of the current interest in the use of early CPAP and the lack of prospective comparisons of this approach with the evidence based intervention of prophylactic or early surfactant, the SUPPORT study was designed to compare these approaches for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design, and the results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324).This report describes the prospective comparison of CPAP and a protocol-directed ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters. These results will be separately reported.

The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a protocol driven minimal ventilator strategy in infants of 24 to 28 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born at a randomizing center without known malformations, for whom a decision had been made to provide full resuscitation, and parental consent had been obtained. The infants were randomized within each center to 2 gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used at all sites for the delivery room administration of CPAP. CPAP or ventilation with PEEP both at a recommended 5 cm H_2O was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU using the T-piece resuscitator or equivalent device and a face mask or nasal prongs. CPAP infants were not to be intubated for surfactant only in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was to be performed only for the standard NRP indications (need ref) including failure to respond to positive pressure ventilation (PPV) with evidence of continuing cyanosis or bradycardia, the need for chest compressions, the need to administer intratracheal medications, or other situations in which the resuscitation team determined that surfactant is urgently required.

NICU management: Intubation was allowed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery. While intubation was never required by protocol, CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour,

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

an arterial $PaCO_2$ > 65 torr documented on a single blood gas within one hour of intubation, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean airway pressure (MAP) < 10 cm H2O, ventilator rate ≤ 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations CPAP infants were treated using NICU standardpractice.

Surfactant Arm: All infants were to be intubated within 1 hour of life and receive surfactant, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30 An FiO2 ≤ 35 with a SpO2 ≥88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate ≤ 20 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and be hemodynamically stable with no evidence of clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard practice.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard practice. For both arms of the trial intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, and thus multiples, were randomized to the same arm of the trial.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, (using the NRN occurrence of death or survival with BPD of 67% using the year 2000 data), and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months (using the NRN occurrence of NDI of 61% using year 2000 data) by 10%. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1312 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the 2 factorial arms.

In addition there was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which required an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks and assigned a diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support. [1617]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each Group who developed their respective outcome measure of survival without BPD at 36 weeks. Adjustment was performed

as pre-specified for gestational age stratum, center and familial clustering using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. A two-sided P value of less than 0.05 was considered statistically significant. An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. (Lan-DeMets spending functions with Pocock (O'Brien-Fleming) boundaries were used to develop stopping rules for interim safety and efficacy monitoring. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and a combination of any of the above events.

The study was approved by Human Subjects Committees at all participating sites and RTI, the NRN data center that managed and analyzed all the data, and parental consent for participation in the trial was required before delivery

Results:

There were 1316 infants enrolled in this trial from Feb 2005 through to Mar 1 2009 . The trial was temporarily suspended by the DSMB because of concerns regarding the oximetry data in November 2005 but after a complete review the trial was continued in February 2006 with no protocol changes. The patient descriptive information for the CPAP versus Surfactant arms is shown in Table 1. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, Apgar scores or race between the 2 treatment groups. The Surfactant group received significantly more

epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant.

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants, and surfactant was given to 14% of the CPAP versus 51% of the surfactant group; 67% of the CPAP infants received surfactant in the delivery room or NICU, compared to 99% of those in the surfactant group (all $p<0.001$). Intubation in the DR occurred in 34% of CPAP infants compared with 93% of surfactant infants, $p<0.001$, Table 2.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post conceptional age was non-significantly reduced for the CPAP group compared with the Surfactant group, 49% versus 54%, (RR 0.91, 05% CI 0.82, 1.00, $p=0.060$) when adjusted for gestational age, center and familial clustering as prespecified. Death during the hospitalization was 4% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata,, 24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, $p=0.03$, Table 4. There was a non-significant reduction in the occurrence of BPD using the need for supplemental oxygen, 40% vs 44%, RR 0.93, 95% CI 0.82, 1.06. Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39% vs 41%, RR 0.99, 95% CI 0.87, 1.14), and a non-significant reduction in the occurrence of death or Physiologic BPD at 36 weeks in the CPAP group, (48% vs 51%, RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room nor any differences in length of stay, or days of oxygen for survivors, or discharge on oxygen. (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, ($p=0.019$). There were no significant

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All infants in the Surfactant arm were intubated, compared with 83% of the CPAP infants who required intubation during their nursery course, ($p<0.001$). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants, 7% vs 13%, p=.0005). The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18] was non- significantly reduced in in the CPAP compared to the surfactant infants, (23% vs 31%, RR=0.75(0,54, 1.05)

Strata Results: 24 – 25 weeks Gestation (post hoc analysis)

There were more non-Hispanic black infants in the CPAP group compared with the Surfactant group. The differences are shown in Table 4 (24-25 wk Strata). CPAP infants had a significantly lower mortality while hospitalized 24% vs 32%, RR=0.74, 95% CI 0.57, 0.98, p=0.03. There was a significantly higher exposure to postnatal steroids for BPD, 20% vs 13%, p=0.02 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata.

26-27 weeks Gestation

There was no difference in mortality for the CPAP vs Surfactant groups, 10% vs 11%. The CPAP infants required fewer days of oxygen, 40.6 vs 47.1, p=0.01, and lesser days of mechanical

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

ventilation, 11.3 vs 14.9, p=0.01, and fewer infants received postnatal steroids for BPD, 3% vs 8%, p<0.01.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare early CPAP with early surfactant given within an hour of life in ELBW infants and the only prospective randomized trial comparing CPAP to any other outcome that enrolled infants of 24 weeks gestation. In a preliminary study we found that 100% of infants of 23 weeks gestation required intubation in the DR, and thus decided that such infants would be unlikely to be successfully treated with CPAP alone following delivery.[19] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[20]

Our study differs from the recently reported COIN trial[15,14] in that we randomized all eligible ELBW infants of consenting families irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven minimal ventilator strategy with infants who all received surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven minimal ventilator strategy was a result of previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a higher threshold approach for intubation and the initiation of mechanical ventilation, and the current practice of a number of NRN units.[6,7] We believed that testing this complete approach would provide a more relevant result as most units currently using early CPAP also tend to have a higher threshold for intubation.

Our study has demonstrated that early CPAP and protocol driven mimimal ventilator strategy when compared with surfactant given within 1 hour of birth was associated with a non-significant decrease in death or survival with BPD as defined by the need for oxygen at 36 weeks from 54% to 49%. We also noted a very significant 8% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.5 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that this lower incidence of death in these infants along with reductions in BPD, ROP, significantly decreased durations of ventilation and oxygen, a decreased need for intubation and exposure to post natal steroids in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant.

We prospectively identified a number of safety outcomes that we chose to follow as investigators. These included the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks, initially defined as pneumothoraces but later altered to include pulmonary interstitial emphysema, pneumomediastinum and pneumopericardium. We did not find an increase in airleaks with the use of early CPAP at 5 cm H2O compared to the use of early surfactant.

The SUPPORT study was a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we did prospectively agree to

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Conclusions:

Compared with the use of surfactant within 1 hour of birth, ELBW infants between 24 and 27 6/7ths weeks gestation at birth treated with CPAP and a protocol driven minimal ventilator strategy have a non significant decreased incidence of death or survival with BPD based on the need for oxygen at 36 weeks PCA with no demonstrable increase in any adverse neonatal outcomes. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence-based alternative to intubation and surfactant.

Are we (the non-subcommittee members) going to get a copy of the outcome data to review before the call? It's a lot to digest and I think the steering committee discussion was suboptimal because people hadn't had a chance to review the data beforehand.

Hi Rose:

University of Rochester:
For the SUPPORT study: no CTSA

Our SUPPORT participation was before the University converted to the CTSA on 9/30/2006. Therefore, the (former) CRC tells me that the appropriate citation is:

"This publication was made possible by Grant Number 5 MO1 RR00044 from the National Center for Research Resources (NCRR), a component of the National Institutes of Health (NIH). Its contents are solely the responsibility of the authors and do not necessarily represent the official views of NCRR or NIH."

I realize you will probably not use all of that wording.
Dale

Subject: Urgent info request: CTSA

Hi,
Please send me an email by November 3 indicating whether or not your site received CTSA support for the SUPPORT main trial. This information is essential for an accurate boilplate.

Thanks
Rose

I have appended my comments and suggested changes to Neil's edits. We also need to think about whether we want to harmonize the titles of the two papers in some manner. Also, in reviewing Wally's paper, I made some other changes to Neil's paper (also attached). Please use this version rather than the one I sent out earlier today.

Thanks

Abhik

Hi Wally
Very nice, succinct. I removed one sentence that I think is redundant in the intro. Marie can you please add all the relevant p values and then we can send out to the Subcommittee
Thanks for a wonderful effort Wally
Neil

Dear Rose, Neil, Marie and Abhik:

Enclosed is the next draft. I have received comments from some of you and from Michele, and I have responded to the issues raised.

I talked with Abhik and he agreed Marie should get a Kaplan Meier plot for mortality (New Fig 2).

I think it is ready to be sent to the rest of the Subcommittee.

Wally

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to either CPAP initiated in the delivery room, and were subsequently treated using a protocol driven minimal ventilator strategy, ~~. Infants randomized~~ or, to surfactant, and were intubated and received surfactant within 60 min minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while in the NICU and receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was 49% in the CPAP group versus 54% in the surfactant group, (RR 0.91, 95% CI 0.82, 1.00, p=0.06 when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.019) and fewer required intubation or post natal steroids for BPD, (p<.001) ~~(p<0.001)~~.

Conclusions: The use of surfactant within 1 hour of birth and conventional mechanical ventilation in ELBW infants between 24 and 27 6/7ths weeks gestation at birth, compared to treatment with CPAP and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

a protocol driven minimal ventilator strategy, did not decrease the incidence of death or survival with BPD at 36 weeks. There was also no demonstrable increase in any adverse neonatal outcomes in infants treated with CPAP. The use of CPAP in such infants is thus an effective evidence based alternative to intubation and surfactant.

Formatted: Font: 11 pt

Introduction:

At the present time, there is no agreement as to the optimal approach to respiratory support for the extremely low birth weight (ELBW) infant following delivery. Positive End Expiratory Pressure (PEEP) has been shown to be of benefit in maintaining functional residual capacity (FRC), and continuous positive airway pressure appears beneficial during cardiopulmonary resuscitation[1]. Gregory et al in 1971 first demonstrated that the use of CPAP started at approximately 5.9 hours (+12.4hrs) for their infants < 1500 gm at birth, improved oxygenation[2] in newborn infants with respiratory distress; these observations were followed by prospective studies that demonstrated improved survival in premature infants treated with early CPAP[3]. A review of prospective studies evaluating early (not delivery room) CPAP in the pre-surfactant, pre-antenatal steroid era found that early CPAP improved survival overall and for infants greater than 1500 gm, and was associated with increased pneumothoraces.[4] A more recent

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

review of prophylactic CPAP started in the delivery room reviewed only 2 available trials and found no significant difference between the CPAP and conventionally managed infants and noted a trend to increased adverse outcomes for the CPAP treated infants.[5]

There is substantial retrospective evidence suggesting a benefit for early CPAP in experiences from both the US and other countries.[678] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following the initiation of early CPAP treatment.[91011]

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[1213] Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI). [14]

The recent COIN trial randomized 610 infants from 25 weeks 0 days to 28 weeks 6 days gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[15] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analyses46, and a reduction in death or the need for oxygen at

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with no difference in death or BPD at 36 weeks.

In view of the current interest in the use of early CPAP and the lack of prospective comparisons of this approach with the evidence based intervention of prophylactic or early surfactant, the SUPPORT study was designed to compare these approaches for the most preterm infants. ~~We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design, and the results for the oximetry study will be reported separately.~~

Comment [AD1]: I think this can be deleted here because we say it in the Methods section.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324).This report describes the prospective comparison of CPAP and a permissive ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also simultaneously randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters. These results will be separately reported.

The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a protocol driven

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

minimal ventilator strategy in infants of 24 to 28 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born at a randomizing center, for which a decision had been made to provide full resuscitation, without known malformations, and for whom parental consent had been obtained antenatally. The infants were randomized within each center to 2 gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.-, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, and thus multiples, were randomized to the same arm of the trial.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used at all sites for the delivery room administration of CPAP. CPAP or ventilation with PEEP both at a recommended 5 cm H_2O was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU using the T-piece resuscitator or equivalent device and a face mask or nasal prongs. CPAP infants were not to be intubated for surfactant only in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was performed only for the standard NRP indications including failure to respond to positive pressure ventilation (PPV) with evidence of continuing cyanosis or bradycardia, the need for chest compressions, the need to administer intratracheal medications, or other situations in which the resuscitation team determined that surfactant is urgently required.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

NICU management: Intubation was performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery. While intubation was never required by protocol, CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean airway pressure (MAP) < 10 cm H2O, ventilator rate < 15 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations CPAP infants were treated using NICU standard of care.

Surfactant Arm: All infants were to be intubated within 1 hour of life and receive surfactant, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30 An FiO2 ≤ 35 with a SpO2 > 88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate $\leq$ 15 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and be hemodynamically stable with no evidence of clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard of care.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard of care. For both arms of the trial intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

~~Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, and thus multiples, were randomized to the same arm of the trial.~~

Comment [AD2]: This is a repeat, and can be deleted.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks by an absolute difference of 10%.~~,~~ ~~(~~Our sample size calculations were based upon~~using~~ the NRN ~~occurrence~~ rate of death or survival with BPD of 67% ~~using~~ from the year 2000 data, a conservative 2% level of significance (to account for a co-primary outcome of death or neurodevelopmental impairment at 18-22 months corrected age), and a conservative outcome rate of 50%.~~), and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months (using the NRN occurrence of NDI of 61% using year 2000 data) by 10%.~~ Based on a historic intra-cluster correlation of 0.12 in this outcome (from analysis of 2000 NRN data), w~~W~~e further increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because ~~as~~ this introduced a clustering effect into the design.~~, and increased the sample sizes by a further~~We inflated the required sample size by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310~~2~~ infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the 2 factorial arms.

Formatted: Font: Bold

Comment [AD3]: I think we need to be consistent in whether we frame the hypothesis as increased survival free of BPD or reduced death/BPD, and the tables should follow that approach.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

In addition there was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which required an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks and assigned a diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support. [16,17]

Formatted: Superscript

Statistical analyses: Intent~~ion~~-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each Group who developed their respective outcome measure of survival without BPD at 36 weeks. Adjustment was performed as pre-specified for gestational age stratum, center and familial clustering using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. A two-sided p~~P~~ value of less than 0.05 was considered statistically significant. An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock and ~~(~~O'Brien-Fleming~~)~~ boundaries were used to develop stopping rules for interim safety and efficacy monitoring respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and a combination of any of the above events.

Formatted: Font: Bold

The study was approved by Human Subjects Committees at all participating sites and RTI, the NRN data center that managed and analyzed all the data, and parental consent for participation in the trial was required before delivery.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Results:

There were 1316 infants enrolled in this trial from Jan 1 2004 through to Mar 1 2009 (Figure 1). The trial was temporarily suspended by the DSMB because of concerns regarding the oximetry data in November 2005 but after a complete review the trial ~~was continued~~resumed in February 2006 with no protocol changes. The patient descriptive information for the CPAP versus Surfactant arms is shown in Table 1. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no statistically significant differences for sex, birth weight, Apgar scores or race between the 2 treatment groups. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant.

Comment [AD4]: This would be the CONSORT flow diagram.

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants, and surfactant was given to 14% of the CPAP versus 51% of the surfactant group; 67% of the CPAP infants received surfactant in the delivery room or NICU, compared to 99% of those in the surfactant group (all $p<0.0001$). Intubation in the DR occurred in 34% of CPAP infants compared with 93% of surfactant infants, $p<0.0001$, Table 2.

There was no statistically significant difference in the primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post conceptional age, between the treatment groups. A trend towards reduced death or BPD was however noted ~~was non-significantly reduced~~ for the CPAP group compared with the Surfactant group, 49% versus 54%, (RR 0.91, 05% CI 0.82, 1.00, p=0.06~~0~~) when adjusted for gestational age, center and familial clustering as prespecified. Death during the hospitalization was 4% lower for the CPAP group

Comment [AD5]: I want to say this upfront just to satisfy the NEJM!

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata,~~,~~ 24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03, Table 4. There was a non-significant reduction in the occurrence of BPD using the need for supplemental oxygen, 40% vs 44%, RR 0.93, 95% CI 0.82, 1.06. Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39% vs 41%, RR 0.99, 95% CI 0.87, 1.14), and a non-significant reduction in the occurrence of death or Physiologic BPD at 36 weeks in the CPAP group, (48% vs 51%, RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room nor any differences in length of stay, or days of oxygen for survivors, or discharge on oxygen. (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.019). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All infants in the Surfactant arm were intubated, compared with 83% of the CPAP infants who required intubation during their nursery course, (p<0.0001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants, 7% vs 13%, p=.0005). There was a trend towards reduced incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18] ~~was non- significantly reduced~~ in ~~in~~ the CPAP compared to the surfactant infants, ~~(~~23% vs 31%, RR=0.75(0,54, 1.05).

Strata Results: 24 – 25 weeks Gestation

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

There were more non-Hispanic black infants in the CPAP group compared with the Surfactant group. The differences are shown in Table 4 (24-25 wk Strata). CPAP infants had a significantly lower mortality while hospitalized, 24% vs 32%, RR=0.74, 95% CI 0.57, 0.98, p=0.03. There was a significantly higher exposure to postnatal steroids for BPD, 20% vs 13%, p=0.02 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this stratuma.

26-27 weeks Gestation

There was no difference in mortality for the CPAP vs Surfactant groups, 10% vs 11%. The CPAP infants required fewer days of oxygen, mean of 40.6 vs 47.1 days, p=0.01, and lesser days of mechanical ventilation, mean of 11.3 vs 14.9 days, p=0.01, and fewer infants received postnatal steroids for BPD, 3% vs 8%, p<0.01.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare early CPAP with early surfactant given within an hour of life in ELBW infants and the only prospective randomized trial comparing CPAP to any other outcome that enrolled infants of 24 weeks gestation. In a preliminary study we found that 100% of infants of 23 weeks gestation required intubation in the DR, and thus decided that such infants would be unlikely to be successfully treated with CPAP alone following delivery.[19] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[20]

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our study differs from the recently reported COIN trial[~~15~~14] in that we randomized all eligible ELBW infants of consenting families irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven minimal ventilator strategy with infants who all received surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven minimal ventilator strategy was a result of previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a very permissive approach for intubation and the initiation of mechanical ventilation, and the current practice of a number of NRN units.[6,7] We believed that testing this complete approach would provide a more relevant result as most units currently using early CPAP also tend to be permissive in their use of intubation.

Formatted: Font: 12 pt, Superscript

Our study has demonstrated that the use of surfactant within 1 hour of birth and conventional mechanical ventilation in ELBW infants between 24 and 27 6/7ths weeks gestation at birth, compared to treatment with CPAP and a protocol driven minimal ventilator strategy, does not decrease the incidence of death or survival with BPD at 36 weeks. Our data indeed suggests that early CPAP ~~and protocol driven mimimal ventilator strategy when~~ compared with surfactant ~~given within 1 hour of birth was~~ is associated with a ~~reduction non-significant~~ decrease in death or survival with BPD as defined by the need for oxygen at 36 weeks from 54% to 49%. We also noted a ~~very~~ substantial (and statistically significant) 8% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.5 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that this lower incidence of death in these infants along with trends

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

towards reductions in BPD, ROP, -significantly decreased durations of ventilation and oxygen, a decreased need for intubation and exposure to post natal steroids in the overall CPAP group without any increase in adverse neonatal outcomes -represents a substantial clinical benefit compared with the initial use of early surfactant~~,~~.

Comment [AD6]: I am worried that this statement will be perceived to be stronger than our data allow. After all, the reduced deaths are only in the 24-24 weekers.

We prospectively identified a number of safety outcomes that we chose to follow as investigators. These included the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of air leaks, initially defined as pneumothoraces but later altered to include pulmonary interstitial emphysema, pneumomediastinum and pneumopericardium. We did not find an increase in air leaks with the use of early CPAP at 5 cm H2O compared to the use of early surfactant.

The SUPPORT study was designed as a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we did prospectively agree to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Conclusions:

Compared with the use of CPAP and a protocol driven minimal ventilator strategy, ~~surfactant within 1 hour of birth~~ ELBW infants between 24 and 27 6/7ths weeks gestation at birth treated with ~~CPAP and a protocol driven minimal ventilator strategy~~ surfactant within 1 hour of birth do

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

not have a ~~non-significant~~ decreased incidence of death or survival with BPD based on the need for oxygen at 36 weeks PCA. There is a strong trend towards reduced death or BPD in the CPAP group with no demonstrable increase in any adverse -neonatal outcomes. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence based alternative to intubation and surfactant.

COMMENT ON TABLES: All tables need to have adjusted p values. Also, if we are presenting a table for the 24-25 weekers, we need to do the same for the 26-27 weekers.

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95%. The primary outcome was a composite of threshold retinopathy of prematurity and/or death. ~~As part of the SUPPORT Trial, infants were also randomized to continuous positive airway pressure and a protocol-driven limited ventilator strategy or to surfactant and ventilation.~~

Comment [AD1]: I don't think we need this in the abstract itself.

Results

Threshold retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28 vs 32%; CI 0.90; RR 0.76, 1.06; P = ___). Death was more frequent in the lower oxygen saturation target group (20 vs 16%; RR 1.27; CI 1.01, 1.60; P = 0.__) and was partially offset by a lower rate of threshold retinopathy (9 vs 18%; RR 0.51, 0.37, 0.71; P = ___).

Comment [AD2]: Both here and in the conclusion, we need to think about how to phrase this – can death be really offset by anything?! Perhaps we can say something like 'An observed benefit of less ROP in the lower sat group was negated by higher mortality in that group'.

Conclusions

Lower oxygen saturation (85-89%) targeting did not significantly decrease the combined outcomes of threshold retinopathy/death but resulted in an increase in mortality that partially offset a decrease in

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

threshold retinopathy. The increased mortality is of concern since~~as~~ lower saturation targeting is increasingly being advocated ~~as it has~~because of its short term retinopathy benefits (Clinical Trials Gov. Number, NCT 00233324).

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] However, in subsequent years, the practice of restricting oxygen supplementation was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6, 7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy[12], and other morbidities. Although a multicenter study [13] could not determine an association between oxygen levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations of lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3,4,5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery was higher in infants cared for in neonatal intensive care units with maximum target oxygen saturation $\geq$ 92% (3.3 $\pm$ 0.3 versus 1.4 $\pm$ 0.2%) or $\geq$ 98% (5.6 $\pm$ 1.1 versus 3.1 $\pm$ 0.3%).[5] The incidence of severe retinopathy requiring ablation therapy was 27% in units where target saturations were 88 to 98% and only 6% in units where the target was 70 to 90% in a retrospective study comparing outcomes at five neonatal intensive care units.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

to 95% resulted in a substantial reduction in retinopathy.[4, 15, 16] However, actual oxygen saturations achieved were not reported. Furthermore, mortality and neurodevelopmental outcomes were not reported. ~~Pulse oximetry has become the standard technique for continuous monitoring of oxygenation.~~ While data from these recent prospective observational and retrospective studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease the incidence of retinopathy of prematurity, there is no conclusive evidence that these oxygenation levels do so without an increase in serious adverse effects, including the possibility of increased risk of death with lower oxygenation as previously reported.

Comment [A3]: Previously stated above

We conducted a 2 x 2 factorial-design multicenter randomized trial of oxygen saturation targeting and protocol-driven limited ventilator strategy. The oxygen saturation part of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of threshold retinopathy of prematurity or death among infants of 24 to 27 weeks gestational age at birth. The ventilation part of this factorial design trial was used to control for the ventilatory approach and test other hypotheses, and will be reported separately.

METHODS

The institutional review boards at all Neonatal Research Network (NRN) clinical centers and at ~~Research Triangle~~RTI International, the independent Data Coordinating Center for the NRN ~~(data center)~~, approved the trial. Written informed consent was obtained from the parent or guardian of each participant before delivery.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Patients

Infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation, without a decision to forego resuscitation were eligible for enrollment at birth. Outborn infants and major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of double-sealed opaque envelopes to oxygen saturation targeting of 85 to 89% or 91 to 95% (the lower and higher oxygen saturation target groups, respectively) ~~with balancing blocks~~using permuted block randomization. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88 to 92% for these oxygen ranges, with an offset of 3% (Massimo Radical Set Pulse Oximeter, Irvine, CA) as previously used to separate oxygen saturations in premature infants.[20] Thus, for example, an oxygen saturation display of 92% would correspond to an actual oxygen saturation of 89% and 95% in the 85-89% and 91-95% target groups, -respectively. The oxygen saturation values displayed reverted to actual values when less than 85% or higher than 95%, the levels of alarm setting recommended in the protocol. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours. Infants weaned to room air but who subsequently received oxygen supplementation before 36 weeks post-menstrual age were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinicians, and not by the research staff. Reports of displayed data by

~~treatment arm and~~ clinical center were provided quarterly for feedback on targeting performance. ~~For the ventilation part of this 2 by 2 factorial design trial, participants were also randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilation strategy..~~

Comment [AD4]: Since this has already been covered in the Introduction, I don't think it needs to be repeated here.

Assessments

Research nurses recorded all data using standardized definitions laid out in the trial Manual of Operations. Data were collected until discharge except for retinopathy. Outcomes included only predefined clinical diagnoses and potential adverse events. The primary outcome was death before discharge and/or threshold retinopathy. Threshold retinopathy of prematurity (New Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[21]) was coded if any of the following findings were present up to 55 weeks post-menstrual age:

Comment [AD5]: These 2 sentences seem a bit confusing and opaque to me; perhaps they need to be expanded upon, or deleted.

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic interventions defined as any of the following: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, vitrectomy, and bevacizumab (Avastin).

~~Follow-up at 18-22 months is being conducted.~~

Statistical analysis

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The primary analysis for the oxygen saturation arm of this factorial trial was a generalized estimating equation (GEE) model that used robust Poisson regression to produce adjusted relative risks comparing incidence rates for infants in each treatment arm who developed the primary outcome. The model produces relative risk estimates adjusted for stratification by center and gestational age as well as for familial clustering due to randomization of multiple births to the same treatment arm. A median actual oxygen saturation value while on oxygen supplementation was determined for each infant to compare the effect of targeting an actual oxygen saturation values between treatment arms.

An absolute difference of 10% between the two treatment groups was considered clinically important. Our sample size calculations were based upon the NRN rate of death or threshold ROP of 50% from the year 2000 data and a conservative 2% level of significance (to account for a co-primary outcome of death or neurodevelopmental impairment at 18-22 months corrected age). Based on a historic intra-cluster correlation of 0.12 in this outcome (from analysis of 2000 NRN data), we further increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because this introduced a clustering effect into the design. We inflated the required sample size by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1310 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the 2 factorial arms.~~To detect this difference, we planned to enroll 1310 infants for 80% power to detect a 10% difference in outcome assuming a baseline estimated rate of 50% of death/threshold retinopathy/surgery. This sample size estimate included an increase by a factor of 1.12 to account for randomizing multiples to the same treatment group and on an increase by a factor of 1.17 to account for the expected attrition after discharge and before follow up. While these sample size calculations allowed for the testing of two co-primary outcomes for the two interventions (oxygen saturation~~

~~targeting and protocol-driven, limited ventilator strategy) of this 2 by 2 factorial trial, the trial was not powered to determine an interaction between the interventions.~~

Comment [AD6]: I made this change so that this section reads almost the same for the 2 papers.

Intent~~ion~~-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the NRN data center. A two-sided p~~P~~ value of less than 0.05 was considered to be statistically significant. Analyses did not include adjustment for multiple comparisons. An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at ~25%, 50%, and 75% of planned enrollment. Lan-DeMets spending functions with Pocock and ~~(~~O'Brien-Fleming~~)~~ boundaries were used to develop stopping rules for interim safety and efficacy monitoring respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of the above events.

RESULTS

1316 infants were enrolled between January 2004 and March 2009 (Figure 1). Enrollment was temporarily paused after evaluation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and Human Development Director because of concerns regarding compliance with oxygen saturation targets. Separate analysis of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns, and continued enrollment was approved.

The baseline characteristics of the lower saturation group and the higher saturation group were similar (Table 1).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Major outcomes

The primary outcome, threshold retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28 vs 32%; CI 0.90; RR 0.76, 1.06; pP=0.____; Table 2). Death before discharge occurred in 130 of the 654 (20%) of the infants in the lower oxygen saturation group versus in 107 of the 662 (16%) of the infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; P=0.04). Comparable results were observed for both gestational age strata. Kaplan Meier Analysis indicated _____ (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Threshold retinopathy was decreased in the lower oxygen saturation targeted group (9 vs 18%; CI 0.51, RR 0.37, 0.71; pP=0._____). Oxygen use at 36 weeks was decreased in the lower oxygen saturation group but bronchopulmonary dysplasia determined by the physiological oxygen saturation test on oxygen at 36 weeks and the composite outcome of bronchopulmonary dysplasia/death did not differ between the treatment groups. Other pre-specified major outcomes did not differ significantly between the two treatment groups (Table 2).

The median oxygen saturation of both groups differed substantially but, as expected, there was substantial overlap (Figure 3). These data indicate that actual oxygen saturation levels are slightly higher than targets in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Table 3). Other measures of resource utilization did not differ as well.

DISCUSSION

Comment [AD7]: As it is, this discussion is currently almost entirely focused on the mortality outcome. I think we need to add discussion on the ROP benefit and the tradeoff between death and ROP, and the treatment implications of this finding.

The recommended ranges of oxygen saturation targeting for very preterm infants have been determined from nonrandomized studies, and restriction of oxygen supplementation is becoming the standard practice.[3, 22] However, there was an increase in mortality when a restrictive oxygen supplementation was practiced in the 1950s and 1960s. Despite not being based on randomized controlled trials and the limited evidence of safety, lower oxygen saturation targeting has been increasingly adopted by units and physicians in an attempt to decrease retinopathy of prematurity. However, in a large multi-center randomized trial we found that even though lower oxygen saturation targeting reduced threshold retinopathy, it also increased the risk for mortality.

This trial was not powered for examining a difference in mortality only between the two oxygen saturation groups. However, this is the largest completed prospective multi-center randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results add to previous data raising the concern that oxygen restriction may increase mortality in very preterm infants. The infants in this trial were more immature than those of any previous trials of oxygen restriction and, thus, may have had a higher susceptibility to the effects of lower oxygen saturation targeting. In addition, aside from the decreased use of oxygen supplementation at 36 weeks, there were no other benefits from oxygen restriction among the outcomes evaluated. The previous data on the increased mortality from oxygen restriction were from studies with lower levels of evidence rather than from randomized controlled trials. It is interesting and worrisome that the combined risk difference observed in the trials from the1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.8% mortality increase in the lower targeted SpO2 group that was observed in our trial.

Comment [AD8]: Was this written before we had the ROP outcomes? Lower sat certainly appears to reduce ROP, specially in the more immature babies.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Restriction of oxygenation in previous randomized controlled trials in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17, 18] However, these trials aimed for saturations of 91 to 94% and 89 to 94% in the lower oxygen saturation group which are closer to the targets of the higher saturation arm in the current trial. The lower target of oxygen saturations or the postnatal age of the intervention may be related to the adverse outcome.

There are several ongoing trials across the world that address the same intervention tested in the current trial as well as a planned prospective meta-analysis.[23] At the present time, it is important that these trials continue and that the investigators and the data safety and monitoring committees of these trials are aware of the results of the current trial so that appropriate decisions can be made regarding their interim analyses, completion of the trials, and dissemination of the data. The current trial raises the concern of adverse hospital outcomes due to oxygen saturation targeting in the 85 to 89% range. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years but at the present time, caution should be exercised regarding oxygen targeting in the low range for extremely premature babies, such as those tested in the current trial.

Neil:

Here are some suggested changes and comments. I tried to tone things down a little more without changing the thrust of the conclusions.

I also wonder whether we should proactively state that although death was a pre-specified secondary outcome, we did not pre-specify looking within strata, but felt compelled to present the death results by strata anyway because of safety concerns.

Also, we are reporting a lot of p values without any multiplicity adjustments. Perhaps we can preempt any criticism on that score by stating that as a limitation in the Discussion (adding that readers are free to apply their own significance cut-off, or take these as exploratory, not confirmatory, results)?

Thanks

Abhik

Hi Everyone
Here is my revised take - please review carefully and see if I have defended our position - I think we make our case. The ROP adds to the benefit and we do not have any increase in any adverse outcomes and I have not overplayed the decrease in death Be well Look forward to your input Neil

Neil
I have the copy of the paper from Tuesday evening that you sent and have the following comments;

The conclusions of the abstract should state something like intubation with surf offers no benefit over cpap in our study. Should we also state that this occurred in the era of antenatal steroid use as a standard practice and the 96 percent of our infants had received them??

In the methods sample size discssion, do we need to inclde the FU power analysis since we are not yet reporting FU??

Discussion - ors is the first trial to do a head-to-head comparison of cpap versus intubation + surf. We should get this in there.

The may Ellen Avery survey paper about BPD from 1987 is not in the references - it may be appropriate to include.

I also pulled the May 2009 NeoProm update.
As of that meeting, the following nmbers were recruited into the trials:

BOOST II australia 658/1200
BOOST II New zealand -291/320
BOOST UK -332/1200
COT -684/1200

Each trial has a dsmc and likely monitoring AE's like mortality. - see the previous email for NICHD and NHLBI discussions.

Thanks for all the effort!!!
This is a landmark study

Rose

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to either CPAP initiated in the delivery room, and were subsequently treated using a protocol driven minimal ventilator strategy, ~~Infants randomized~~ or, to surfactant, and were intubated and received surfactant within 60 min minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while in the NICU and receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was 49% in the CPAP group versus 54% in the surfactant group, (RR 0.91, 95% CI 0.82, 1.00, p=0.06 when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.019) and fewer required intubation or post natal steroids for BPD, (p<.001) ~~(p<0.001)~~.

Conclusions: The use of surfactant within 1 hour of birth and conventional mechanical ventilation in ELBW infants between 24 and 27 6/7ths weeks gestation at birth, compared to treatment with CPAP and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

a protocol driven minimal ventilator strategy, did not decrease the incidence of death or survival with BPD at 36 weeks. There was also no demonstrable increase in any adverse neonatal outcomes in infants treated with CPAP. The use of CPAP in such infants is thus an effective evidence based alternative to intubation and surfactant.

Formatted: Font: 11 pt

Introduction:

At the present time, there is no agreement as to the optimal approach to respiratory support for the extremely low birth weight (ELBW) infant following delivery. Positive End Expiratory Pressure (PEEP) has been shown to be of benefit in maintaining functional residual capacity (FRC), and continuous positive airway pressure appears beneficial during cardiopulmonary resuscitation[1]. Gregory et al in 1971 first demonstrated that the use of CPAP started at approximately 5.9 hours (+12.4hrs) for their infants < 1500 gm at birth, improved oxygenation[2] in newborn infants with respiratory distress; these observations were followed by prospective studies that demonstrated improved survival in premature infants treated with early CPAP[3]. A review of prospective studies evaluating early (not delivery room) CPAP in the pre-surfactant, pre-antenatal steroid era found that early CPAP improved survival overall and for infants greater than 1500 gm, and was associated with increased pneumothoraces.[4] A more recent

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

review of prophylactic CPAP started in the delivery room reviewed only 2 available trials and found no significant difference between the CPAP and conventionally managed infants and noted a trend to increased adverse outcomes for the CPAP treated infants.[5]

There is substantial retrospective evidence suggesting a benefit for early CPAP in experiences from both the US and other countries.[678] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following the initiation of early CPAP treatment.[91011]

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[1213] Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI). [14]

The recent COIN trial randomized 610 infants from 25 weeks 0 days to 28 weeks 6 days gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[15] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analyses~~6~~4, and a reduction in death or the need for oxygen at

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with no difference in death or BPD at 36 weeks.

In view of the current interest in the use of early CPAP and the lack of prospective comparisons of this approach with the evidence based intervention of prophylactic or early surfactant, the SUPPORT study was designed to compare these approaches for the most preterm infants. ~~We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design, and the results for the oximetry study will be reported separately.~~

Comment [AD1]: I think this can be deleted here because we say it in the Methods section.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324).This report describes the prospective comparison of CPAP and a permissive ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also simultaneously randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters. These results will be separately reported.

The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a protocol driven

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

minimal ventilator strategy in infants of 24 to 28 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born at a randomizing center, for which a decision had been made to provide full resuscitation, without known malformations, and for whom parental consent had been obtained antenatally. The infants were randomized within each center to 2 gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.-, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, and thus multiples, were randomized to the same arm of the trial.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used at all sites for the delivery room administration of CPAP. CPAP or ventilation with PEEP both at a recommended 5 cm H_2O was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU using the T-piece resuscitator or equivalent device and a face mask or nasal prongs. CPAP infants were not to be intubated for surfactant only in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was performed only for the standard NRP indications including failure to respond to positive pressure ventilation (PPV) with evidence of continuing cyanosis or bradycardia, the need for chest compressions, the need to administer intratracheal medications, or other situations in which the resuscitation team determined that surfactant is urgently required.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

NICU management: Intubation was performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery. While intubation was never required by protocol, CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean airway pressure (MAP) < 10 cm H2O, ventilator rate < 15 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations CPAP infants were treated using NICU standard of care.

Surfactant Arm: All infants were to be intubated within 1 hour of life and receive surfactant, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30 An FiO2 ≤ 35 with a SpO2 > 88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate $\leq$ 15 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and be hemodynamically stable with no evidence of clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard of care.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard of care. For both arms of the trial intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

~~Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, and thus multiples, were randomized to the same arm of the trial.~~

Comment [AD2]: This is a repeat, and can be deleted.

Formatted: Font: Bold

Comment [AD3]: I think we need to be consistent in whether we frame the hypothesis as increased survival free of BPD or reduced death/BPD, and the tables should follow that approach.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks by an absolute difference of 10%.~~,~~ ~~(~~Our sample size calculations were based upon~~using~~ the NRN ~~occurrence~~ rate of death or survival with BPD of 67% ~~using~~ from the year 2000 data, a conservative 2% level of significance (to account for two outcomes for each arm of the 2 by 2 factorial design), and a conservative outcome rate of 50%.~~), and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months (using the NRN occurrence of NDI of 61% using year 2000 data) by 10%.~~ Based on a historic intra-cluster correlation of 0.12 in this outcome (from analysis of 2000 NRN data), w~~W~~e further increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment, because ~~as~~ this introduced a clustering effect into the design.~~, and increased the sample sizes by a further~~We inflated the required sample size by an additional 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1312 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the 2 factorial arms.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

In addition there was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which required an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks and assigned a diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support. [16,17]

Formatted: Superscript

Statistical analyses: Intent~~ion~~-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each Group who developed their respective outcome measure of survival without BPD at 36 weeks. Adjustment was performed as pre-specified for gestational age stratum, center and familial clustering using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. A two-sided p~~P~~ value of less than 0.05 was considered statistically significant. An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock and ~~(~~O'Brien-Fleming~~)~~ boundaries were used to develop stopping rules for interim safety and efficacy monitoring respectively. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and a combination of any of the above events.

Formatted: Font: Bold

The study was approved by Human Subjects Committees at all participating sites and RTI, the NRN data center that managed and analyzed all the data, and parental consent for participation in the trial was required before delivery.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Results:

There were 1316 infants enrolled in this trial from Jan 1 2004 through to Mar 1 2009 . The trial was temporarily suspended by the DSMB because of concerns regarding the oximetry data in November 2005 but after a complete review the trial ~~was continued~~resumed in February 2006 with no protocol changes. The patient descriptive information for the CPAP versus Surfactant arms is shown in Table 1. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no statistically significant differences for sex, birth weight, Apgar scores or race between the 2 treatment groups. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant.

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants, and surfactant was given to 14% of the CPAP versus 51% of the surfactant group; 67% of the CPAP infants received surfactant in the delivery room or NICU, compared to 99% of those in the surfactant group (all $p<0.0001$). Intubation in the DR occurred in 34% of CPAP infants compared with 93% of surfactant infants, $p<0.0001$, Table 2.

There was no statistically significant difference in the primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post conceptional age, between the treatment groups. A trend towards reduced death or BPD was however noted ~~was non-significantly reduced~~ for the CPAP group compared with the Surfactant group, 49% versus 54%, (RR 0.91, 05% CI 0.82, 1.00, p=0.06~~0~~) when adjusted for gestational age, center and familial clustering as prespecified. Death during the hospitalization was 4% lower for the CPAP group

Comment [AD4]: I want to say this upfront just to satisfy the NEJM!

overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata,~~,~~ 24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03, Table 4. There was a non-significant reduction in the occurrence of BPD using the need for supplemental oxygen, 40% vs 44%, RR 0.93, 95% CI 0.82, 1.06. Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39% vs 41%, RR 0.99, 95% CI 0.87, 1.14), and a non-significant reduction in the occurrence of death or Physiologic BPD at 36 weeks in the CPAP group, (48% vs 51%, RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room nor any differences in length of stay, or days of oxygen for survivors, or discharge on oxygen. (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.019). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All infants in the Surfactant arm were intubated, compared with 83% of the CPAP infants who required intubation during their nursery course, (p<0.0001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants, 7% vs 13%, p=.0005). There was a trend towards reduced incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18] ~~was non-significantly reduced~~ in ~~in~~ the CPAP compared to the surfactant infants, ~~(~~23% vs 31%, RR=0.75(0,54, 1.05).

Strata Results: 24 – 25 weeks Gestation

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

There were more non-Hispanic black infants in the CPAP group compared with the Surfactant group. The differences are shown in Table 4 (24-25 wk Strata). CPAP infants had a significantly lower mortality while hospitalized, 24% vs 32%, RR=0.74, 95% CI 0.57, 0.98, p=0.03. There was a significantly higher exposure to postnatal steroids for BPD, 20% vs 13%, p=0.02 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this stratuma.

26-27 weeks Gestation

There was no difference in mortality for the CPAP vs Surfactant groups, 10% vs 11%. The CPAP infants required fewer days of oxygen, mean of 40.6 vs 47.1 days, p=0.01, and lesser days of mechanical ventilation, mean of 11.3 vs 14.9 days, p=0.01, and fewer infants received postnatal steroids for BPD, 3% vs 8%, p<0.01.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare early CPAP with early surfactant given within an hour of life in ELBW infants and the only prospective randomized trial comparing CPAP to any other outcome that enrolled infants of 24 weeks gestation. In a preliminary study we found that 100% of infants of 23 weeks gestation required intubation in the DR, and thus decided that such infants would be unlikely to be successfully treated with CPAP alone following delivery.[19] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[20]

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our study differs from the recently reported COIN trial[1514] in that we randomized all eligible ELBW infants of consenting families irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven minimal ventilator strategy with infants who all received surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven minimal ventilator strategy was a result of previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a very permissive approach for intubation and the initiation of mechanical ventilation, and the current practice of a number of NRN units.[6,7] We believed that testing this complete approach would provide a more relevant result as most units currently using early CPAP also tend to be permissive in their use of intubation.

Formatted: Font: 12 pt, Superscript

Our study has demonstrated that the use of surfactant within 1 hour of birth and conventional mechanical ventilation in ELBW infants between 24 and 27 6/7ths weeks gestation at birth, compared to treatment with CPAP and a protocol driven minimal ventilator strategy, does not decrease the incidence of death or survival with BPD at 36 weeks. Our data indeed suggests that early CPAP ~~and protocol driven mimimal ventilator strategy when~~ compared with surfactant ~~given within 1 hour of birth was~~ is associated with a ~~reduction non significant~~ decrease in death or survival with BPD as defined by the need for oxygen at 36 weeks from 54% to 49%. We also noted a ~~very~~ substantial (and statistically significant) 8% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.5 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that this lower incidence of death in these infants along with trends

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

towards reductions in BPD, ROP, -significantly decreased durations of ventilation and oxygen, a decreased need for intubation and exposure to post natal steroids in the overall CPAP group without any increase in adverse neonatal outcomes -represents a substantial clinical benefit compared with the initial use of early surfactant~~,~~.

Comment [AD5]: I am worried that this statement will be perceived to be stronger than our data allow. After all, the reduced deaths are only in the 24-24 weekers.

We prospectively identified a number of safety outcomes that we chose to follow as investigators. These included the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of air leaks, initially defined as pneumothoraces but later altered to include pulmonary interstitial emphysema, pneumomediastinum and pneumopericardium. We did not find an increase in air leaks with the use of early CPAP at 5 cm H2O compared to the use of early surfactant.

The SUPPORT study was designed as a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we did prospectively agree to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Conclusions:

Compared with the use of CPAP and a protocol driven minimal ventilator strategy, ~~surfactant within 1 hour of birth~~ ELBW infants between 24 and 27 6/7ths weeks gestation at birth treated with ~~CPAP and a protocol driven minimal ventilator strategy~~ surfactant within 1 hour of birth do

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

not have a ~~non-significant~~ decreased incidence of death or survival with BPD based on the need for oxygen at 36 weeks PCA. There is a strong trend towards reduced death or BPD in the CPAP group with no demonstrable increase in any adverse -neonatal outcomes. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence based alternative to intubation and surfactant.

COMMENT ON TABLES: All tables need to have adjusted p values. Also, if we are presenting a table for the 24-25 weekers, we need to do the same for the 26-27 weekers. We also need a CONSORT flow chart that should be referenced in the Results section.

Hi Everyone
Here is my revised take - please review carefully and see if I have defended our position - I think we make our case. The ROP adds to the benefit and we do not have any increase in any adverse outcomes and I have not overplayed the decrease in death
Be well
Look forward to your input
Neil

Subject: Neil's paper

Neil
I have the copy of the paper from Tuesday evening that you sent and have the following comments;

The conclusions of the abstract should state something like intubation with surf offers no benefit over cpap in our study. Should we also state that this occurred in the era of antenatal steroid use as a standard practice and the 96 percent of our infants had received them??

In the methods sample size discssion, do we need to inclde the FU power analysis since we are not yet reporting FU??

Discussion - ors is the first trial to do a head-to-head comparison of cpap versus intubation + surf. We should get this in there.

The may Ellen Avery survey paper about BPD from 1987 is not in the references - it may be appropriate to include.

I also pulled the May 2009 NeoProm update.
As of that meeting, the following nmbers were recruited into the trials:

BOOST II australia 658/1200
BOOST II New zealand -291/320
BOOST UK -332/1200
COT -684/1200

Each trial has a dsmc and likely monitoring AE's like mortality. - see the previous email for NICHD and NHLBI discussions.

Thanks for all the effort!!!
This is a landmark study

Rose

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of 24 0/7ths weeks to 27 6/7ths weeks. Infants were randomized to CPAP initiated in the delivery room and were subsequently treated using a protocol driven minimal ventilator. Infants randomized to surfactant were intubated and received surfactant within 60 min minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while in the NICU and receiving supplemental oxygen.

Results: The study enrolled 1316 infants. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks was 49% in the CPAP group versus 54% in the surfactant group, (RR 0.91, 95% CI 0.82, 1.00, p=0.06 when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the CPAP infants, (24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, p=0.03). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.019) and fewer required intubation or post natal steroids for BPD, (p<.001) (p<0.001).

Conclusions: The use of CPAP in such infants is an effective evidence based alternative to intubation and surfactant.

Introduction:

At the present time, there is no agreement as to the optimal approach to respiratory support for the extremely low birth weight (ELBW) infant following delivery. Positive End Expiratory Pressure (PEEP) has been shown to be of benefit in maintaining functional residual capacity (FRC), and continuous positive airway pressure appears beneficial during cardiopulmonary resuscitation[1]. Gregory et al in 1971 first demonstrated that the use of CPAP started at approximately 5.9 hours (+12.4hrs) for their infants < 1500 gm at birth, improved oxygenation[2] in newborn infants with respiratory distress; these observations were followed by prospective studies that demonstrated improved survival in premature infants treated with early CPAP[3]. A review of prospective studies evaluating early (not delivery room) CPAP in the pre-surfactant, pre-antenatal steroid era found that early CPAP improved survival overall and for infants greater than 1500 gm, and was associated with increased pneumothoraces.[4] A more recent review of prophylactic CPAP started in the delivery room reviewed only 2 available trials and found no significant difference between the CPAP and conventionally managed infants and noted a trend to increased adverse outcomes for the CPAP treated infants.[5]

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

There is substantial retrospective evidence suggesting a benefit for early CPAP in experiences from both the US and other countries.[678] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following the initiation of early CPAP treatment.[91011]

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[1213] Overall surfactant has not been reported to significantly reduce BPD, but may do so for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI). [14]

The recent COIN trial randomized 610 infants from 25 weeks 0 days to 28 weeks 6 days gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[15] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analyses46, and a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with no difference in death or BPD at 36 weeks.

In view of the current interest in the use of early CPAP and the lack of prospective comparisons of this approach with the evidence based intervention of prophylactic or early surfactant, the

SUPPORT study was designed to compare these approaches for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design, and the results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network (Clinical Trials Gov. Number, NCT 00233324).This report describes the prospective comparison of CPAP and a permissive ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters. These results will be separately reported.

The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a protocol driven minimal ventilator strategy in infants of 24 to 28 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born at a randomizing center, for which a decision had been made to provide full resuscitation, without

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

known malformations, and for whom parental consent had been obtained. The infants were randomized within each center to 2 gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used at all sites for the delivery room administration of CPAP. CPAP or ventilation with PEEP both at a recommended 5 cm H_2O was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU using the T-piece resuscitator or equivalent device and a face mask or nasal prongs. CPAP infants were not to be intubated for surfactant only in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was performed only for the standard NRP indications including failure to respond to positive pressure ventilation (PPV) with evidence of continuing cyanosis or bradycardia, the need for chest compressions, the need to administer intratracheal medications, or other situations in which the resuscitation team determined that surfactant is urgently required.

NICU management: Intubation was performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery. While intubation was never required by protocol, CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean airway pressure (MAP) < 10 cm H2O, ventilator rate < 15 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations CPAP infants were treated using NICU standard of care.

Surfactant Arm: All infants were to be intubated within 1 hour of life and receive surfactant, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30 An FiO2 ≤ 35 with a SpO2 > 88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate ≤ 15 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and be hemodynamically stable with no evidence of clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard of care.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard of care. For both arms of the trial intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, and thus multiples, were randomized to the same arm of the trial.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, (using the NRN occurrence of death or survival with BPD of 67% using the year 2000 data), and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months (using the NRN occurrence of NDI of 61% using year 2000 data) by 10%. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1312 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the 2 factorial arms.

In addition there was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which required an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks and assigned a diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support. [16,17]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each Group who developed their respective outcome measure of survival without BPD at 36 weeks. Adjustment was performed

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

as pre-specified for gestational age stratum, center and familial clustering using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. A two-sided P value of less than 0.05 was considered statistically significant. An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock (O'Brien-Fleming) boundaries were used to develop stopping rules for interim safety and efficacy monitoring. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and a combination of any of the above events.

The study was approved by Human Subjects Committees at all participating sites and RTI, the NRN data center that managed and analyzed all the data, and parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled in this trial from Jan 1 2004 through to Mar 1 2009 . The trial was temporarily suspended by the DSMB because of concerns regarding the oximetry data in November 2005 but after a complete review the trial was continued in February 2006 with no protocol changes. The patient descriptive information for the CPAP versus Surfactant arms is shown in Table 1. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, Apgar scores or race between the 2 treatment groups. The Surfactant group received significantly more

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant.

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants, and surfactant was given to 14% of the CPAP versus 51% of the surfactant group; 67% of the CPAP infants received surfactant in the delivery room or NICU, compared to 99% of those in the surfactant group (all $p<0.0001$). Intubation in the DR occurred in 34% of CPAP infants compared with 93% of surfactant infants, $p<0.0001$, Table 2.

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post conceptional age was non-significantly reduced for the CPAP group compared with the Surfactant group, 49% versus 54%, (RR 0.91, 05% CI 0.82, 1.00, $p=0.060$) when adjusted for gestational age, center and familial clustering as prespecified. Death during the hospitalization was 4% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata,, 24% vs 32%, RR 0.74, 95% CI 0.57, 0.98, $p=0.03$, Table 4. There was a non-significant reduction in the occurrence of BPD using the need for supplemental oxygen, 40% vs 44%, RR 0.93, 95% CI 0.82, 1.06. Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39% vs 41%, RR 0.99, 95% CI 0.87, 1.14), and a non-significant reduction in the occurrence of death or Physiologic BPD at 36 weeks in the CPAP group, (48% vs 51%, RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room nor any differences in length of stay, or days of oxygen for survivors, or discharge on oxygen. (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, ($p=0.019$). There were no significant

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All infants in the Surfactant arm were intubated, compared with 83% of the CPAP infants who required intubation during their nursery course, ($p<0.0001$). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants, 7% vs 13%, p=.0005). The incidence of retinopathy of prematurity using the new Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[18] was non- significantly reduced in in the CPAP compared to the surfactant infants, (23% vs 31%, RR=0.75(0,54, 1.05)

Strata Results: 24 – 25 weeks Gestation

There were more non-Hispanic black infants in the CPAP group compared with the Surfactant group. The differences are shown in Table 4 (24-25 wk Strata). CPAP infants had a significantly lower mortality while hospitalized 24% vs 32%, RR=0.74, 95% CI 0.57, 0.98, p=0.03. There was a significantly higher exposure to postnatal steroids for BPD, 20% vs 13%, p=0.02 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata.

26-27 weeks Gestation

There was no difference in mortality for the CPAP vs Surfactant groups, 10% vs 11%. The CPAP infants required fewer days of oxygen, 40.6 vs 47.1, p=0.01, and lesser days of mechanical

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

ventilation, 11.3 vs 14.9, p=0.01, and fewer infants received postnatal steroids for BPD, 3% vs 8%, p<0.01.

Discussion:

The SUPPORT trial is the first prospective randomized multicenter trial to compare early CPAP with early surfactant given within an hour of life in ELBW infants and the only prospective randomized trial comparing CPAP to any other outcome that enrolled infants of 24 weeks gestation. In a preliminary study we found that 100% of infants of 23 weeks gestation required intubation in the DR, and thus decided that such infants would be unlikely to be successfully treated with CPAP alone following delivery.[19] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[20]

Our study differs from the recently reported COIN trial[15,16] in that we randomized all eligible ELBW infants of consenting families irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP and a protocol driven minimal ventilator strategy with infants who all received surfactant within 1 hour of birth. Our method of using early CPAP and a protocol driven minimal ventilator strategy was a result of previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a very permissive approach for intubation and the initiation of mechanical ventilation, and the current practice of a number of NRN units.[6,7] We believed that testing this complete approach would provide a more relevant result as most units currently using early CPAP also tend to be permissive in their use of intubation.

Formatted: Font: 12 pt, Superscript

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Our study has demonstrated that early CPAP and protocol driven mimimal ventilator strategy when compared with surfactant given within 1 hour of birth was associated with a reduction non-significant decrease in death or survival with BPD as defined by the need for oxygen at 36 weeks from 54% to 49%. We also noted a very significant 8% reduction in death in the CPAP infants of our 24 to 25 week strata, resulting in a number needed to treat of 12.5 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that this lower incidence of death in these infants along with reductions in BPD, ROP, significantly decreased durations of ventilation and oxygen, a decreased need for intubation and exposure to post natal steroids in the overall CPAP group without any increase in adverse neonatal outcomes represents a substantial clinical benefit compared with the initial use of early surfactant,.

We prospectively identified a number of safety outcomes that we chose to follow as investigators. These included the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks, initially defined as pneumothoraces but later altered to include pulmonary interstitial emphysema, pneumomediastinum and pneumopericardium. We did not find an increase in airleaks with the use of early CPAP at 5 cm H2O compared to the use of early surfactant.

The SUPPORT study was designed as a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we did prospectively

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

agree to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival without neurodevelopmental impairment at 18 to 22 months and these results will be presented after all survivors have been assessed.

Conclusions:

Compared with the use of surfactant within 1 hour of birth ELBW infants between 24 and 27 6/7ths weeks gestation at birth treated with CPAP and a protocol driven minimal ventilator strategy have a non significant decreased incidence of death or survival with BPD based on the need for oxygen at 36 weeks PCA with no demonstrable increase in any adverse neonatal outcomes. Early CPAP is associated with a significant reduction in mortality in the most immature infants. The use of CPAP in such infants is an effective evidence based alternative to intubation and surfactant.

Stephanie
I looked at the boilerplate in detail for Wally's paper.
I will repoll the steering committee regarding CTSA support and this will need to be accurately updated.
Emory has indicated an alternate author.
For individual site grant numbers, please list the U10 awards first (they funded the vast majority of study costs, the GCRCs and CTSA funding was much less).

Please affirm/check the following items:
Mickey's institution name - I believe this is North Shore, but check with him or his staff. Also his tenure for the NRN should be 2006-present in stead of 2011.

Did indiana indicate that
Faithe Hamer had a role (in addition to FU)?

RTI listing should also include Dennis Wallace, PhD.

Does UCSD need to include Rene Bridges? She responded to several of the queries I sent over time.

Does Iowa need to list Gretchen - one of the other research nurses?

University of New Mexico - Conra Lacy is not listed, yet she is the lead coordinator. -please check.

UT southwestern - Diana Vasil is not listed and has also been involved with query resolution.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The DSMC is missing and needs to be listed.

We should also list the NHLBI folks. I will get a lis of them.

Let me know if you need help getting responses. This is a pivotal trial and I want to get it right.

Thanks so much for putting this together.

Rose

Dear Rose, Neil, Marie and Abhik:

Enclosed is the next draft. I have received comments from some of you and from Michele, and I have responded to the issues raised.

I talked with Abhik and he agreed Marie should get a Kaplan Meier plot for mortality (New Fig 2).

I think it is ready to be sent to the rest of the Subcommittee.

Neil and Wally -
Thanks to the two of you for the immense commitment to the SUPPORT trial.
I truly appreciate the professional as well as personal investment that you have made to help babies!!

Just in case -
(b) (6)

I can be reached via Blackberry and cell phone (703-395-(b) (6)

Unfortunately, we have an issue with the land line phone (b) (6)
(b) (6) so I may not have immediate access to computer applications. If needed, I can get to an internet wireless or line hook up with short notice.

I will be back in the office on Wednesday, november 4. I will be available for the dsmc on Wednesday.

With warmest regards,

Rose

Subject: Re: Manuscript

Wally

Thanks for quickly turning this around.

We refer ro nonrandomized studies in several sections of the paper. Is observational a better word?

There is no citation of the STOP-ROP paper in the manuscript. Although this looked at saturation levels in pretheshold ROP, it should probably be listed.

Methods - end of the first paragraph - delete "before delivery" as part of the consent process. Although this occrred in the vast majority, there were a few that occurred after delivery for a variety of reasons.

Wold it be possible to include the scatter graph of actual versus monitor oximetry levels included in the stdy protocl in the supplementary/appendix materials? We explain this 3 percent offset in the methods on page 12, bt the graph really shows it to those who are visually oriented.

At the bottom of page 12 we stated that sat targets were maintained by "clinicians.". It may be more accurate to say adjustments.... were performed by "NICU or clinical staff.". This way, everyone (nrse, md, resp therapist) are included and it is acucrate reporting.

In the methods section (page 13) nder assessments - should we (or do we even have space) report abot the 14 day safety monitoring??

Leave 18-22 month FU out of the methods section on page 13 I this shold be incluuded in the discussion.

Bottom of page 14 I should we add one sentence about the first dsmc look at the data that occurred due

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

to concern with compliance with sat levels are the part of the investigators as this happened prior to 25 percent enrollment? I suggest "dsmc evaluated sat data upon reqest of investigators to evaluate compliance after enrollment of XX infants.". You do explain this in the results and it leaves the reader wondering why we did this.

Results - first line page 15 I enrollment started in Feb 2005 not Jan 2004 (I think).

Discussion - second line - you stated "standard" practice. I recommend changing this to "common" practice as there was no AAP guideline or otherwise indicating "standard."

Page 17 - end paragraph- reviewers may want to know abot the lower sat infants and deaths (ron goldberg's comment at the sc meeting.

The last paragraph of the discussion should restate the primary outcome and the two significant otcones of ROP and BPD benefit.

Table 1 has 655 in low sat group and 661 in high sat group. On table 2 many of the denominators are 654 in low sat group and there is a denominator of 662 on several of the high sat outcomes - we need to fix this.

Also, threshold rop/death says 17/605 for low sat group (should be 170/) and high sat group says 198.616.

Figure 1 - is there a way to have "pregnancies" assessed for eligibility?". That is actually how this nfolded.

For figure 2 - is there any way to "statistically" assess if we reached an adequate separation between the two groups??

Also -
I also pulled the May 2009 NeoProm confidential update.
As of that meeting, the following nmbers were recruited into the trials:

BOOST II australia 658/1200
BOOST II New zealand -291/320
BOOST UK -332/1200
COT -684/1200

Each trial has a dsmc and likely monitoring AE's like mortality. I have spoken to NICHD and NHLBI leadership. The other trials are enrolling children following delivery. Our dsmc meets Nov 4 -the leadership would like input from or DSMC prior to any possible confidential dscussions with other dsmc's. Also the observed mortality between the two sat groups (16 and 20 percent) is tighter than the nrn range of mortality from historical data provided to our dsmc (9.5-32 percent deaths by day 14).

Hi Wally

Very nice, succinct. I removed one sentence that I think is redundant in the intro. Marie can you please add all the relevant p values and then we can send out to the Subcommittee

Thanks for a wonderful effort Wally

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95%. The primary outcome was a composite of threshold retinopathy of prematurity and/or death. As part of the SUPPORT Trial, infants were also randomized to continuous positive airway pressure and a protocol-driven limited ventilator strategy or to surfactant and ventilation.

Results

Threshold retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28 vs 32%; CI 0.90; RR 0.76, 1.06; P = ___). Death was more frequent in the lower oxygen saturation target group (20 vs 16%; RR 1.27; CI 1.01, 1.60; P = 0.__) and was partially offset a lower rate of threshold retinopathy (9 vs 18%; RR 0.51, 0.37, 0.71; P = ___).

Conclusions

Lower oxygen saturation (85-89%) targeting did not significantly decrease combined outcomes of threshold retinopathy/death but resulted in an increase in mortality that partially offset a decrease in

threshold retinopathy. The increased mortality is of concern as lower saturation targeting is increasingly being advocated as it has short term retinopathy benefits (Clinical Trials Gov. Number, NCT 00233324).

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] However, in subsequent years, the practice of restricting oxygen supplementation was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6, 7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy[12], and other morbidities. Although a multicenter study [13] could not determine an association between oxygen levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations of lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3,4,5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery was higher in infants cared for in neonatal intensive care units with maximum target oxygen saturation $\geq$ 92% (3.3 $\pm$ 0.3 versus 1.4 $\pm$ 0.2%) or $\geq$ 98% (5.6 $\pm$ 1.1 versus 3.1 $\pm$ 0.3%).[5] The incidence of severe retinopathy requiring ablation therapy was 27% in units where target saturations were 88 to 98% and only 6% in units where the target was 70 to 90% in a retrospective study comparing outcomes at five neonatal intensive care units.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83

to 95% resulted in a substantial reduction in retinopathy.[4, 15, 16] However, actual oxygen saturations achieved were not reported. Furthermore, mortality and neurodevelopmental outcomes were not reported. ~~Pulse oximetry has become the standard technique for continuous monitoring of oxygenation.~~ While data from these recent prospective observational and retrospective studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease the incidence of retinopathy of prematurity, there is no conclusive evidence that these oxygenation levels do so without an increase in serious adverse effects, including the possibility of increased risk of death with lower oxygenation as previously reported.

Comment [A1]: Previously stated above

We conducted a 2 x 2 factorial-design multicenter randomized trial of oxygen saturation targeting and protocol-driven limited ventilator strategy. The oxygen saturation part of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of threshold retinopathy of prematurity or death among infants of 24 to 27 weeks gestational age at birth. The ventilation part of this factorial design trial was used to control for the ventilatory approach and test other hypotheses.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at Research Triangle International, the independent Data Coordinating Center for the NRN (data center) approved the trial. Written informed consent was obtained from the parent or guardian of each participant before delivery.

Patients

Infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation, without a decision to forego resuscitation were eligible for enrollment at birth. Outborn infants and major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of double-sealed opaque envelopes to oxygen saturation targeting of 85 to 89% or 91 to 95% (the lower and higher oxygen saturation target groups, respectively) with balancing blocks. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88 to 92% for these oxygen ranges, with an offset of 3% (Massimo Radical Set Pulse Oximeter, Irvine, CA) as previously used to separate oxygen saturations in premature infants.[20] Thus, for example, an oxygen saturation display of 92% would correspond to an actual oxygen saturation of 89% and 95% in the 85-89% and 91-95% target groups, respectively. The oxygen saturation values displayed reverted to actual values when less than 85% or higher than 95%, the levels of alarm setting recommended in the protocol. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours. Infants weaned to room air but who subsequently received oxygen supplementation before 36 weeks post-menstrual age were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinicians, not by the research staff. Reports of displayed data by treatment arm and clinical center were

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

provided quarterly for feedback on targeting performance. For the ventilation part of this 2 by 2 factorial design trial, participants were also randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilation strategy..

Assessments

Research nurses recorded all data using standardized definitions. Data were collected until discharge except for retinopathy. Outcomes included only predefined clinical diagnoses and potential adverse events. The primary outcome was death before discharge and/or threshold retinopathy. Threshold retinopathy of prematurity (New Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[21]) was coded if any of the following findings were present up to 55 weeks post-menstrual age:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic interventions defined as any of the following: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, vitrectomy, and bevacizumab (Avastin).

Follow-up at 18-22 months is being conducted.

Statistical analysis

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The primary analysis for the oxygen saturation arm of this factorial trial was a generalized estimating equation (GEE) model that used robust Poisson regression to produce adjusted relative risks comparing incidence rates for infants in each treatment arm who developed the primary outcome. The model produces relative risk estimates adjusted for stratification by center and gestational age as well as for familial clustering due to randomization of multiple births to the same treatment arm. A median actual oxygen saturation value while on oxygen supplementation was determined for each infant to compare the effect of targeting an actual oxygen saturations between treatment arms.

An absolute difference of 10% between the two treatment groups was considered clinically important. To detect this difference, we planned to enroll 1310 infants for 80% power to detect a 10% difference in outcome assuming a baseline estimated rate of 50% of death/threshold retinopathy/surgery. This sample size estimate included an increase by a factor of 1.12 to account for randomizing multiples to the same treatment group and on an increase by a factor of 1.17 to account for the expected attrition after discharge and before follow up. While these sample size calculations allowed for the testing of two co-primary outcomes for the two interventions (oxygen saturation targeting and protocol-driven, limited ventilator strategy) of this 2 by 2 factorial trial, the trial was not powered to determine an interaction between the interventions. Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. A two-sided P value of less than 0.05 was considered to be statistically significant. Analyses did not include adjustment for multiple comparisons. An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at ~25%, 50%, and 75% of planned enrollment. Lan-DeMets spending functions with Pocock

(O'Brien-Fleming) boundaries were used to develop stopping rules for interim safety and efficacy monitoring. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of the above events.

RESULTS

1316 infants were enrolled between January 2004 and March 2009 (Figure 1). Enrollment was temporarily paused after evaluation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and Human Development Director because of concerns regarding compliance with oxygen saturation targets. Separate analysis of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns, and continued enrollment was approved.

The baseline characteristics of the lower saturation group and the higher saturation group were similar (Table 1).

Major outcomes

The primary outcome, threshold retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28 vs 32%; CI 0.90; RR 0.76, 1.06; P=0.____; Table 2). Death before discharge occurred in 130 of the 654 (20%) of the infants in the lower oxygen saturation group versus in 107 of the 662 (16%) of the infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; P=0.04). Comparable results were observed for both gestational age strata. Kaplan Meier Analysis indicated _____ (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Threshold retinopathy was decreased in the lower oxygen saturation targeted group (9 vs 18%; CI 0.51, RR 0.37, 0.71; P=0._____).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Oxygen use at 36 weeks was decreased in the lower oxygen saturation group but bronchopulmonary dysplasia determined by the physiological oxygen saturation test on oxygen at 36 weeks and bronchopulmonary dysplasia/death did not differ between the treatment groups. Other pre-specified major outcomes did not differ significantly between the two treatment groups (Table 2).

The median oxygen saturation of both groups differed substantially but, as expected, there was overlap (Figure 3). These data indicate that actual oxygen saturation levels are slightly higher than targets in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Table 3). Other measures of resource utilization did not differ as well.

DISCUSSION

The recommended ranges of oxygen saturation targeting for very preterm infants have been determined from nonrandomized studies, and restriction of oxygen supplementation is becoming the standard practice.[3, 22] However, there was an increase in mortality when a restrictive oxygen supplementation was practiced in the 1950s and 1960s. Despite not being based on randomized controlled trials and the limited evidence of safety, lower oxygen saturation targeting has been increasingly adopted by units and physicians in an attempt to decrease retinopathy of prematurity. However, even though lower oxygen saturation targeting reduced threshold retinopathy, it also increased the risk for mortality.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

This trial was not powered for a difference in mortality only between the two oxygen saturation groups. However, this is the largest completed prospective multi-center randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results add to previous data raising the concern that oxygen restriction may increase mortality in very preterm infants. The infants in this trial were more immature than those of any previous trials of oxygen restriction and, thus, may have had a higher susceptibility to the effects of lower oxygen saturation targeting. In addition, aside from the decreased use of oxygen supplementation at 36 weeks, there were no other benefits from oxygen restriction among the outcomes evaluated. The previous data on the increased mortality from oxygen restriction were from studies with lower levels of evidence rather than from randomized controlled trials. It is interesting and worrisome that the combined risk difference observed in the trials from the1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.8% mortality increase in the lower targeted SpO2 group that was observed in our trial.

Restriction of oxygenation in previous randomized controlled trials in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17, 18] However, these trials aimed for saturations of 91 to 94% and 89 to 94% in the lower oxygen saturation group which are closer to the targets of the higher saturation arm in the current trial. The lower target of oxygen saturations or the postnatal age of the intervention may be related to the adverse outcome.

There are several ongoing trials across the world that address the same intervention tested in the current trial as well as a planned prospective meta-analysis.[23] At the present time, it is important that these trials continue and that the investigators and the data safety and monitoring committees of these trials are aware of the results of the current trial so that appropriate decisions can be made regarding their interim

analyses, completion of the trials, and dissemination of the data. The current trial raises the concern of adverse hospital outcomes due to oxygen saturation targeting in the 85 to 89% range. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years but at the present time, caution should be exercised regarding oxygen targeting in the low range for extremely premature babies, such as those tested in the current trial.

Dear Rose, Neil, Marie and Abhik:

Enclosed is the next draft. I have received comments from some of you and from Michele, and I have responded to the issues raised.

I talked with Abhik and he agreed Marie should get a Kaplan Meier plot for mortality (New Fig 2).

I think it is ready to be sent to the rest of the Subcommittee.

Wally

Acknowledgements

The National Institutes of Health, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the National Heart, Lung, and Blood Institute (NHLBI) provided grant support for the Neonatal Research Network's SUPPORT Trial (Recruitment 2005-2009).

Data collected at participating sites of the NICHD Neonatal Research Network (NRN) were transmitted to RTI International, the data coordinating center (DCC) for the network, which stored, managed and analyzed the data for this study. On behalf of the NRN, Drs. Abhik Das (DCC Principal Investigator) and Marie Gantz (DCC Statistician) had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the data analysis.

We are indebted to our medical and nursing colleagues and the infants and their parents who agreed to take part in this study. The following investigators, in addition to those listed as authors, participated in this study:

NRN Steering Committee Chairs: Alan H. Jobe, MD PhD, University of Cincinnati (2003-2006); Michael S. Caplan, MD, University of Chicago, Pritzker School of Medicine (2006-2011).

ABSTRACT

Background

Non randomized studies suggest that the incidence of retinopathy decreases in premature infants with exposure to oxygenation levels lower than previously maintained. However, the range of oxygen saturations that reduces retinopathy without increasing adverse outcomes is not known.

Methods

1316 infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation born at 20 centers of the NICHD Neonatal Research Network were randomly assigned at birth to oxygen saturation targets of 85 to 89% or 91 to 95%. The primary outcome was a composite of threshold retinopathy of prematurity and/or death. As part of the SUPPORT Trial, infants were also randomized to continuous positive airway pressure and a protocol-driven limited ventilator strategy or to surfactant and ventilation.

Results

Threshold retinopathy/death did not differ between the lower and higher oxygen saturation target groups (28 vs 32%; CI 0.90; RR 0.76, 1.06; P = ___). Death was more frequent in the lower oxygen saturation target group (20 vs 16%; RR 1.27; CI 1.01, 1.60; P = 0.__) and was partially offset a lower rate of threshold retinopathy (9 vs 18%; RR 0.51, 0.37, 0.71; P = ___).

Conclusions

Lower oxygen saturation (85-89%) targeting did not significantly decrease combined outcomes of threshold retinopathy/death but resulted in an increase in mortality that partially offset a decrease in

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

threshold retinopathy. The increased mortality is of concern as lower saturation targeting is increasingly being advocated as it has short term retinopathy benefits (Clinical Trials Gov. Number, NCT 00233324).

INTRODUCTION

Retinopathy of prematurity remains an important cause of blindness and other visual disabilities in prematurely born infants. The incidence of retinopathy of prematurity increased with exposure to unrestricted oxygen in premature infants in randomized controlled trials performed in the 1950s.[1] However, in subsequent years, the practice of restricting oxygen supplementation was estimated to result in an excess of 16 deaths per case of blindness prevented.[2] More recent data suggest that oxygen saturation levels previously thought to be in the upper limits of normal may increase the risk of retinopathy of prematurity.[3-5] Oxygen toxicity may also increase the risk of mortality[6, 7], bronchopulmonary dysplasia[8-10], periventricular leukomalacia[11], cerebral palsy[12], and other morbidities. Although a multicenter study [13] could not determine an association between oxygen levels and retinopathy, a single center cohort study using transcutaneous oxygen monitoring supported the association of retinopathy with exposure to arterial oxygen levels $\geq$ 80 mmHg.[14]

Pulse oximetry allows clinicians to utilize continuous oxygen saturations to target oxygenation. Associations of lower oxygen saturation targeting and a lower incidence of retinopathy have been reported in recent years.[3,4,5,15,16] In a survey study of 144 neonatal intensive care units, the rate of retinal ablation surgery was higher in infants cared for in neonatal intensive care units with maximum target oxygen saturation $\geq$ 92% (3.3 $\pm$ 0.3 versus 1.4 $\pm$ 0.2%) or $\geq$ 98% (5.6 $\pm$ 1.1 versus 3.1 $\pm$ 0.3%).[5] The incidence of severe retinopathy requiring ablation therapy was 27% in units where target saturations were 88 to 98% and only 6% in units where the target was 70 to 90% in a retrospective study comparing outcomes at five neonatal intensive care units.[3] Rates of mortality and cerebral palsy did not differ between these units. In three other studies, a policy of oxygen saturation targeting of approximately 83

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

to 95% resulted in a substantial reduction in retinopathy.[4, 15, 16] However, actual oxygen saturations achieved were not reported. Furthermore, mortality and neurodevelopmental outcomes were not reported. Pulse oximetry has become the standard technique for continuous monitoring of oxygenation. While data from these recent prospective observational and retrospective studies suggest that maintenance of oxygenation at ranges lower than previously used may decrease the incidence of retinopathy of prematurity, there is no conclusive evidence that these oxygenation levels do so without an increase in serious adverse effects, including the possibility of increased risk of death with lower oxygenation as previously reported.

We conducted a 2 x 2 factorial-design multicenter randomized trial of oxygen saturation targeting and protocol-driven limited ventilator strategy. The oxygen saturation part of the trial tested the effect of a lower oxygen saturation target range (85-89%) compared to a higher oxygen saturation target range (91-95%) on the incidence of threshold retinopathy of prematurity or death among infants of 24 to 27 weeks gestational age at birth. The ventilation part of this factorial design trial was used to control for the ventilatory approach and test other hypotheses.

METHODS

The institutional review boards at all Neonatal Research Network clinical centers and at Research Triangle International, the independent Data Coordinating Center for the NRN (data center) approved the trial. Written informed consent was obtained from the parent or guardian of each participant before delivery.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Patients

Infants of $24^{0/7}$ to $27^{6/7}$ weeks gestation, without a decision to forego resuscitation were eligible for enrollment at birth. Outborn infants and major congenital anomalies were excluded. Multiple births were randomized to the same treatment arm.

Enrollment and treatment

Deliveries were stratified by center and by gestational age ($24^{0/7}$ to $25^{6/7}$ weeks or $26^{0/7}$ to $27^{6/7}$ weeks). They were randomly assigned by means of double-sealed opaque envelopes to oxygen saturation targeting of 85 to 89% or 91 to 95% (the lower and higher oxygen saturation target groups, respectively) with balancing blocks. Deliveries were randomized as a unit; thus, multiples were randomized to the same arm of the trial. Masking was maintained using electronically-altered pulse oximeters with output display of 88 to 92% for these oxygen ranges, with an offset of 3% (Massimo Radical Set Pulse Oximeter, Irvine, CA) as previously used to separate oxygen saturations in premature infants.[20] Thus, for example, an oxygen saturation display of 92% would correspond to an actual oxygen saturation of 89% and 95% in the 85-89% and 91-95% target groups, respectively. The oxygen saturation values displayed reverted to actual values when less than 85% or higher than 95%, the levels of alarm setting recommended in the protocol. Oxygen saturation targeting with altered pulse oximetry was initiated within the first two hours after birth and was continued until 36 weeks post-menstrual age or until the infant remained on room air and off the ventilator/continuous positive airway pressure for more than 72 hours. Infants weaned to room air but who subsequently received oxygen supplementation before 36 weeks post-menstrual age were placed back on the assigned study pulse oximeter. Adjustments in supplemental oxygen to maintain the target oxygen saturation between 88-92% were performed by the clinicians, not by the research staff. Reports of displayed data by treatment arm and clinical center were

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

provided quarterly for feedback on targeting performance. For the ventilation part of this 2 by 2 factorial design trial, participants were also randomly assigned to continuous positive airway pressure with a protocol-driven limited ventilatory strategy or to prophylactic/early surfactant with a protocol-driven conventional ventilation strategy..

Assessments

Research nurses recorded all data using standardized definitions. Data were collected until discharge except for retinopathy. Outcomes included only predefined clinical diagnoses and potential adverse events. The primary outcome was death before discharge and/or threshold retinopathy. Threshold retinopathy of prematurity (New Type 1 threshold per Early Treatment of Retinopathy [ETROP] Cooperative Group[21]) was coded if any of the following findings were present up to 55 weeks post-menstrual age:

If in zone 1: Stage 3 retinopathy of prematurity, even without plus disease

Plus disease with any stage retinopathy of prematurity

If in zone II: Plus disease with stage 2 retinopathy of prematurity

Plus disease with stage 3 retinopathy of prematurity

Surgical ophthalmologic interventions defined as any of the following: laser therapy, cryotherapy, laser/cryotherapy, scleral buckle, vitrectomy, and bevacizumab (Avastin).

Follow-up at 18-22 months is being conducted.

Statistical analysis

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The primary analysis for the oxygen saturation arm of this factorial trial was a generalized estimating equation (GEE) model that used robust Poisson regression to produce adjusted relative risks comparing incidence rates for infants in each treatment arm who developed the primary outcome. The model produces relative risk estimates adjusted for stratification by center and gestational age as well as for familial clustering due to randomization of multiple births to the same treatment arm. A median actual oxygen saturation value while on oxygen supplementation was determined for each infant to compare the effect of targeting an actual oxygen saturations between treatment arms.

An absolute difference of 10% between the two treatment groups was considered clinically important. To detect this difference, we planned to enroll 1310 infants for 80% power to detect a 10% difference in outcome assuming a baseline estimated rate of 50% of death/threshold retinopathy/surgery. This sample size estimate included an increase by a factor of 1.12 to account for randomizing multiples to the same treatment group and on an increase by a factor of 1.17 to account for the expected attrition after discharge and before follow up. While these sample size calculations allowed for the testing of two co-primary outcomes for the two interventions (oxygen saturation targeting and protocol-driven, limited ventilator strategy) of this 2 by 2 factorial trial, the trial was not powered to determine an interaction between the interventions. Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. All analyses were conducted at the data center. A two-sided P value of less than 0.05 was considered to be statistically significant. Analyses did not include adjustment for multiple comparisons. An independent Data Safety and Monitoring Committee appointed by the Director of the National Institute of Child Health and Human Development reviewed the primary outcomes, adverse events, and other interim results at ~25%, 50%, and 75% of planned enrollment. Lan-DeMets spending functions with Pocock

(O'Brien-Fleming) boundaries were used to develop stopping rules for interim safety and efficacy monitoring. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage, and a combination of any of the above events.

RESULTS

1316 infants were enrolled between January 2004 and March 2009 (Figure 1). Enrollment was temporarily paused after evaluation by the Data Safety and Monitoring Committee and decision of the National Institutes of Child Health and Human Development Director because of concerns regarding compliance with oxygen saturation targets. Separate analysis of the oximetry data while on room air versus while on oxygen supplementation resolved the concerns, and continued enrollment was approved.

The baseline characteristics of the lower saturation group and the higher saturation group were similar (Table 1).

Major outcomes

The primary outcome, threshold retinopathy and/or death before discharge, did not differ between the lower and higher oxygen saturation groups (28 vs 32%; CI 0.90; RR 0.76, 1.06; P=0.____; Table 2). Death before discharge occurred in 130 of the 654 (20%) of the infants in the lower oxygen saturation group versus in 107 of the 662 (16%) of the infants in the higher oxygen saturation group (RR 1.27; CI 1.01, 1.60; P=0.04). Comparable results were observed for both gestational age strata. Kaplan Meier Analysis indicated _____ (Figure 2). Mortality in the first and second weeks after birth was not significantly different between the two treatment groups (Table 2). Threshold retinopathy was decreased in the lower oxygen saturation targeted group (9 vs 18%; CI 0.51, RR 0.37, 0.71; P=0._____).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Oxygen use at 36 weeks was decreased in the lower oxygen saturation group but bronchopulmonary dysplasia determined by the physiological oxygen saturation test on oxygen at 36 weeks and bronchopulmonary dysplasia/death did not differ between the treatment groups. Other pre-specified major outcomes did not differ significantly between the two treatment groups (Table 2).

The median oxygen saturation of both groups differed substantially but, as expected, there was overlap (Figure 3). These data indicate that actual oxygen saturation levels are slightly higher than targets in both treatment groups. The duration of oxygen supplementation was shorter in the lower oxygen saturation group but the duration of mechanical ventilation, continuous positive airway pressure, and nasal synchronized intermittent mandatory ventilation did not differ (Table 3). Other measures of resource utilization did not differ as well.

DISCUSSION

The recommended ranges of oxygen saturation targeting for very preterm infants have been determined from nonrandomized studies, and restriction of oxygen supplementation is becoming the standard practice.[3, 22] However, there was an increase in mortality when a restrictive oxygen supplementation was practiced in the 1950s and 1960s. Despite not being based on randomized controlled trials and the limited evidence of safety, lower oxygen saturation targeting has been increasingly adopted by units and physicians in an attempt to decrease retinopathy of prematurity. However, even though lower oxygen saturation targeting reduced threshold retinopathy, it also increased the risk for mortality.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

This trial was not powered for a difference in mortality only between the two oxygen saturation groups. However, this is the largest completed prospective multi-center randomized trial to test the effect of lower versus higher oxygen saturation targeting, and the results add to previous data raising the concern that oxygen restriction may increase mortality in very preterm infants. The infants in this trial were more immature than those of any previous trials of oxygen restriction and, thus, may have had a higher susceptibility to the effects of lower oxygen saturation targeting. In addition, aside from the decreased use of oxygen supplementation at 36 weeks, there were no other benefits from oxygen restriction among the outcomes evaluated. The previous data on the increased mortality from oxygen restriction were from studies with lower levels of evidence rather than from randomized controlled trials. It is interesting and worrisome that the combined risk difference observed in the trials from the1950s was a 4.9% increase in mortality in the oxygen restricted group[1], which is close to the 3.8% mortality increase in the lower targeted SpO2 group that was observed in our trial.

Restriction of oxygenation in previous randomized controlled trials in preterm infants beyond the first weeks of life did not show trends for increased mortality in the lower saturation target groups.[17, 18] However, these trials aimed for saturations of 91 to 94% and 89 to 94% in the lower oxygen saturation group which are closer to the targets of the higher saturation arm in the current trial. The lower target of oxygen saturations or the postnatal age of the intervention may be related to the adverse outcome.

There are several ongoing trials across the world that address the same intervention tested in the current trial as well as a planned prospective meta-analysis.[23] At the present time, it is important that these trials continue and that the investigators and the data safety and monitoring committees of these trials are aware of the results of the current trial so that appropriate decisions can be made regarding their interim

analyses, completion of the trials, and dissemination of the data. The current trial raises the concern of adverse hospital outcomes due to oxygen saturation targeting in the 85 to 89% range. Further information from the ongoing randomized controlled trials that evaluate lower versus higher oxygen saturation targeting will become available in the next years but at the present time, caution should be exercised regarding oxygen targeting in the low range for extremely premature babies, such as those tested in the current trial.

Subject: Fwd: ANS manuscript follow-up

Hi Dr. Carlo-

Just wanted to summarize what still needs to be done and we go from here regarding the antenatal steroids manuscript:

1) Redo the existing analysis to extend to 2006 or 2007 (2007 would be a 15 year cohort). This would impact all existing figures and tables, including:
- Figure 1: rates of ANS administration by GA (22-25 weeks) over the study period
- Table 1: demographics of study population
- Table 2: rates of death and morbidities and RR to compare ANS/no ANS in each GA group (22-25 weeks)
- Figure 2: Cox regression of time to death comparing ANS/no ANS (I don't have this figure; is this ANS vs. no ANS in only 22-23 weekers or all GAs?)
- Table 3: 18-22 month outcomes
- redo interaction analyses (no figure/table in manuscript)

**Alexis can contact Scott to start working on this

2) additional analyses to consider
- adding a second Y axis (or separate symbols) to Figure 1 to reflect the proportion of 22-23 weekers as a percentage of the study population over time
- adding a "death or major morbidity" (DOMM) composite outcome to Table 2; consider adding ROP to the major morbidities (prior suggestion from Rose on my initial GDB proposal)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

- since an updated analysis would cover such a long study period, consider assessing 23 weekers (and also 22 weekers if their composite data after re-analysis suggests a benefit) for the outcomes of DOMM and Death/NDI and comparing by time epochs to assess to improvements in care over time (I'm thinking 3 epochs: either 3 5-year epochs or pre ACOG/immediately post ACOG/most recent (though I'm not sure there will be sufficient numbers for the earliest epoch); depending on the opinions of the committee, this could also be reversed into survival without morbidity and survival without NDI
- since we are going to have a larger cohort, additional neonatal variables could be added to the 18-22 month outcomes model (i.e. NEC, sepsis, severe IVH/PVL, postnatal steroids, BPD, maybe center) Maybe this was already done, but I didn't see it in my version of the manuscript

**Perhaps Wally can discuss any/all of these with the subcommittee members to determine which to proceed with

3) refresh introduction based on updated 2008 ACOG statement, revise results section based on new analyses, add to discussion section (new articles from 2007/08)

**Alexis can start working on this now

Depending on what additional analyses are done, would it be appropriate to separate this into early and late outcomes manuscripts? It might be interesting to explore the interaction data more if this is the case.

Have a good weekend-
Alexis

Subject: NRN Support trial data

Dear Dr. Maddox,

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The NRN's SUPPORT trial data analysis for the primary outcome is complete and we want to bring it to your attention. This trial was a factorial design comparing low oxygen vs. high oxygen by two hours of age; the other comparison was CPAP vs. intubation with surfactant in the delivery room. Attached are some slides with data on the primary analyses. (I am sending this email on behalf of Rose who is at the NRN meeting today).

The primary outcome of death or bronchopulmonary dysplasia for the ventilation arm is no difference between CPAP versus intubation with surfactant, but a strong trend and significant secondary outcomes for the CPAP arm, especially in babies born at 24-25 weeks.

For the low vs. high oxygen comparison, there is no difference in the primary outcome of death or ROP. However there is a significant increase in death (predefined secondary outcome) in the lower saturation group (20%) versus the higher saturation group (16%). Offsetting this, is a significantly lower rate of ROP (9%) in the lower saturation group compared to the higher saturation group (18%). This suggests that there is a (b) (5) [redacted]

There are ongoing saturation trials around the world and we are weighing whether we should share the results confidentially (if that is possible) of the significant increase in death with the DSMCs of the ongoing trials. The ongoing trials have a primary outcome of death or neurodevelopmental impairment at 18-22 months. All of these trials recruit infants after birth; the SUPPORT trial consented mothers prior to delivery. Further, gestational age entry criteria may be slightly different.

The infants are being followed for 18-22 month outcome and the DSMC will meet on November 4th – at that meeting they will review the available follow-up data.

Would you be available for a call to discuss this sometime today or tomorrow?
Warmest regards,
Rose and cathy

Subject: RE: NRN Support trial data

Carol and Dorothy,
I am attaching and explaining what we have thus far. I have attached T2S major outcomes for the high and low saturation groups. The low sat group had a (b) (5) Clearly follow up is warranted.

We do not yet have analyses on (b) (5) .

I have also attached T3 BPD which shows (b) (5) If you go to the second table on the T3 BPD document, you will see that a (b) (5)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

(b) (5) .

If you look at T2 Other outcomes table, you will see that the (b) (5)

I think we have some of the other requested info (b) (5) and I will find them and send them.

I am over at the Bolger center until about 3 today at the NRN Follow Up PI meeting.

Let me know if you have other questions. There has not been a cause of death analysis at this point.

Regards
Rose

Carol and Dorothy-
Thank you for your support for the SUPPORT study. The subcommittee and steering committee met yesterday and today and has some concerns regarding (b) (5) (b) (5) I am forwarding the primary outcome information and our specific questions for NICHD leadership. I know Carol will be at the dsmc meeting next week.

Your thoughts would be very helpful as there are 3 saturation trials occurring around the world currently. Again- I want to express my thanks for all you involvement and spport.

Rose

Subject: NRN Support trial data

Dear Dr. Maddox,

The NRN's SUPPORT trial data analysis for the primary outcome is complete and we want to bring it to your attention. This trial was a factorial design comparing low oxygen vs. high oxygen by two hours of age; the other comparison was CPAP vs. intubation with surfactant in the delivery room. Attached are some slides with data on the primary analyses. (I am sending this email on behalf of Rose who is at the NRN meeting today).

The primary outcome of death or bronchopulmonary dysplasia for the ventilation arm is no difference between CPAP versus intubation with surfactant, but a strong trend and significant secondary outcomes for the CPAP arm, especially in babies born at 24-25 weeks.

For the low vs. high oxygen comparison, there is no difference in the primary outcome of death or ROP. However there is a significant increase in death (predefined secondary outcome) in the lower saturation group (20%) versus the higher saturation group (16%). Offsetting this, is a significantly lower rate of ROP (9%) in the lower saturation group compared to the higher saturation group (18%). This suggests that there is a (b) (5)

There are ongoing saturation trials around the world and we are weighing whether we should share the results confidentially (if that is possible) of the significant increase in death with the DSMCs of the ongoing trials. The ongoing trials have a primary outcome of death or neurodevelopmental impairment at 18-22 months. All of these trials recruit infants after birth; the SUPPORT trial consented mothers prior to delivery. Further, gestational age entry criteria may be slightly different.

th

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The infants are being followed for 18-22 month outcome and the DSMC will meet on November 4 – at that meeting they will review the available follow-up data.

Would you be available for a call to discuss this sometime today or tomorrow?
Warmest regards,
Rose and cathy

Subject: RE: Confidential FW: NRN Support trial data
Date: Friday, October 30, 2009 12:15:44 PM
Attachments: T1 Patient Description - 30OCT09.doc
Cause of Death - 30OCT09.doc.rtf

The gender difference in the CPAP/surfactant arm has been consistently p=0.06 (it was like that in August when we looked at it and still is). The difference in the oxygen saturation arm is more like p=0.15. The tables with the DR intervention variables are attached, as is information on cause of death.

Subject: RE: Confidential FW: NRN Support trial data

It appears that gender differences are not statistically significant for either arm after all the data were in. Marie can address the other question, but there may be some delay because she is also trying to get the final report out to the DSMC.

Thanks

Abhik

Subject: Confidential FW: NRN Support trial data

I have been in correspondence with our NICHD and NHLBI leadership for SUPPORT to decide whether or not we have a safety issue that would warrant informing the other dsmc's. Please keep this correspondence confidential for now. I recall that a gender analysis was done - do you have this. Also, Carol is suggesting a cause of death look. Can you send me the table with DR intervention differences in the ventilatory arm?
Thanks
Rose

Carol and Dorothy-
Thank you for your support for the SUPPORT study. The subcommittee and steering committee met yesterday and today and has some concerns regarding the (b) (5) [redacted]. I am forwarding the primary outcome information and our specific questions for NICHD leadership. I know Carol will be at the dsmc meeting next week.

Your thoughts would be very helpful as there are 3 saturation trials occurring around the world currently. Again- I want to express my thanks

Cause of Death for CPAP vs. Surfactant
Where GA is 24-25 weeks

Variable	Category	CPAP (N=68)	Surfactant (N=90)
Contributory cause of death (NG03e, NG03, NG05)	1=RDS	19% (13/68)	34% (31/90)
	2=BPD	15% (10/68)	8% (7/90)
	3=Infection	21% (14/68)	17% (15/90)
	4=NEC	15% (10/68)	18% (16/90)
	5=CNS Insult	16% (11/68)	6% (5/90)
	6=Immaturity	4% (3/68)	6% (5/90)
	7=Other	10% (7/68)	12% (11/90)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Cause of Death for CPAP vs. Surfactant
Where GA is 26-27 weeks

Variable	Category	CPAP (N=41)	Surfactant (N=38)
Contributory cause of death (NG03e, NG03, NG05)	1=RDS	22% (9/41)	24% (9/38)
	2=BPD	5% (2/41)	13% (5/38)
	3=Infection	29% (12/41)	13% (5/38)
	4=NEC	10% (4/41)	18% (7/38)
	5=CNS Insult	5% (2/41)	8% (3/38)
	6=Immaturity	2% (1/41)	3% (1/38)
	7=Other	27% (11/41)	21% (8/38)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Cause of Death for High vs. Low SpO2

Variable	Category	High SpO2 (N=107)	Low SpO2 (N=130)
Contributory cause of death (NG03e, NG03, NG05)	1=RDS	29% (31/107)	24% (31/130)
	2=BPD	9% (10/107)	11% (14/130)
	3=Infection	20% (21/107)	19% (25/130)
	4=NEC	13% (14/107)	18% (23/130)
	5=CNS Insult	8% (9/107)	9% (12/130)
	6=Immaturity	3% (3/107)	5% (7/130)
	7=Other	18% (19/107)	14% (18/130)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Cause of Death for High vs. Low SpO2
Where GA is 24-25 weeks

Variable	Category	High SpO2 (N=73)	Low SpO2 (N=85)
Contributory cause of death (NG03e, NG03, NG05)	1=RDS	29% (21/73)	27% (23/85)
	2=BPD	12% (9/73)	9% (8/85)
	3=Infection	18% (13/73)	19% (16/85)
	4=NEC	12% (9/73)	20% (17/85)
	5=CNS Insult	8% (6/73)	12% (10/85)
	6=Immaturity	4% (3/73)	6% (5/85)
	7=Other	16% (12/73)	7% (6/85)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Cause of Death for High vs. Low SpO2
Where GA is 26-27 weeks

Variable	Category	High SpO2 (N=34)	Low SpO2 (N=45)
Contributory cause of death (NG03e, NG03, NG05)	1=RDS	29% (10/34)	18% (8/45)
	2=BPD	3% (1/34)	13% (6/45)
	3=Infection	24% (8/34)	20% (9/45)
	4=NEC	15% (5/34)	13% (6/45)
	5=CNS Insult	9% (3/34)	4% (2/45)
	6=Immaturity	0% (0/34)	4% (2/45)
	7=Other	21% (7/34)	27% (12/45)

"Other" causes of death specified by current classification in COD table

Contributory cause of death (NG03e, NG03, NG05)=1=RDS

Obs	Other COD specified on NG03e, NG03 or NG05
1	extreme prematurity, RDS, suspected sepsis

Contributory cause of death (NG03e, NG03, NG05)=2=BPD

Obs	Other COD specified on NG03e, NG03 or NG05
2	bpd with multi-systaem organ failure,developed abd. compartment syndrome post-op stricture repair
3	Early onset sepsis & BPD w/severe intracranial hemorrhage.
4	PAHN, Liver Failure, CLD, Resp Failure
5	Endocarditis, Staph pneumonia, multiple pneumothoraces, cystic abscess in lung and advanced BPD
6	Cardiopulmonary arrest due to Pulmonary hypertension & Systemic hypotension & chronic lung disease

Contributory cause of death (NG03e, NG03, NG05)=3=Infection

Obs	Other COD specified on NG03e, NG03 or NG05
7	disseminated Candidiasis
8	pneumonia, sepsis (Blood and lung cultures (+) for S. Aureus, E. Cloacae)
9	proven NEC, sepsis, extreme prematurity
10	extreme prematurity, suspected pulmonary hypoplasia, pneumonia, presumed sepsis
11	ELBW, acute renal failure, severe lung disease, pneumonia, proven sepsis, hypocalcemia
12	septic shock, cardio-respiratory failure, renal failure
13	extreme prematurity, and sepsis
14	extreme prematurity, ecoli sepsis,meningitis
15	Pseudomonas sepsis, acute resp. failure, renal failure
16	pulmonary hypoplasia, clinical sepsis
17	suspected sepsis, DIC, and cerebellar hemorrhage
18	bilateral chylothoraces, sepsis, meconium peritonitis

Contributory cause of death (NG03e, NG03, NG05)=5=CNS Insult

Obs	Other COD specified on NG03e, NG03 or NG05
19	Severe IVH, Pulmonary hemorrhage, HMD, PIE
20	Severe IVH and Pulmonary Hemorrhage
21	Pulmonary hypoplasia with severe intraparenchymal IVH
22	Renal failure and Intraventricular hemorrhage

Contributory cause of death (NG03e, NG03, NG05)=6=Immaturity

Obs	Other COD specified on NG03e, NG03 or NG05
23	severe IUGR
24	prematurity, pulmonary hypertension,cardiorespiratory failure
25	extreme prematurity, severe pulmonary insufficiency

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

"Other" causes of death specified by current classification in COD table

Contributory cause of death (NG03e, NG03, NG05)=7=Other

Obs	Other COD specified on NG03e, NG03 or NG05
26	extensive hemorrhage mid brain,brain stem,thalamic with uncal herniation and hydrocephaly
27	Respiratory failure
28	Pulmonary hemorrhage
29	liver failure
30	renal failure; DIC
31	liver failure with bleeding; ost. sites
32	PPHN-persistent pulmonary hypertension of neonate
33	intravascular hemorrhage before birth
34	per autopsy cause is exsanguination
35	pulmonary hypertension, pulmonary hypoplasia
36	pulmonary hypoplasia, chroramnionitis
37	Pulmonary Hypoplasia
38	twin to twin transfusion syndrome
39	massive pulmonary hemorrhage
40	pulmonary hemorrhage
41	pulmonary hypoplasia
42	Lung hypoplasia
43	hypoplastic lung syndrome due to pprom
44	Massive pulmonary hemorrhage without RDS
45	pulmonary hypoplasia due to multiple congenital anomalies
46	MULTI SYSTEM ORGAN FAILURE
47	severe hypoplastic lungs
48	renal failure;
49	severe pulmonary hypertension
50	tetralogy of fallot 7 other multiple cardiac anomalies renal anomalies(possiblby va cterl syndrome
51	cardiac arrythmia
52	extensive hemorrhage of rt. chest cavity after chest tube placement
53	perforation of right atrium by tip of PICC line
54	transposition of the great vessels
55	PREMATURITY, PULMONARY HYPOPLESIA, EXOPHAGEAL ATRESIA, SKELETAL ANNOMALIES
56	probable pulmonary hypoplasia

Hi,

In follow up to yesterday's publication discussion, please send me your vote by November 3 for NRN Primary study manuscripts for author order following subcommittee members:

1._____ Leave as is (50% credit for absolute number recruited and 50% credit for enrolled/eligible)

2.__x___ Change to absolute number recruited

3._____ Change to a combination of absolute number and percent enrolled/eligible (AND SEND YOUR PROPOSAL WITH YOUR VOTE)

Rose

See correspondence below

Both Susie Buchter and Anthony Plazza at Emory worked on SUPPORT. I would propose that Susie be an author on the CPAP /vent paper and that Anthony be an authore on the O2 sat paper-- They will of course review and comment on the papers

THANKS

BJS

----- Original Message -----

I would like to be on the CPAP/vent paper, but would be pleased for Anthony to be on sat paper.
Thanks for including us both.

There will be 2 primary papers from SUPPORT-- a CPAP/vent paper and a sat paper
Although I named you as the Emory PI on the paper, Anthony was a very strong collaborator. Are you OK with my asking the NRN to have you as the Emory author on one paper and Anthony on the other?

Hi Rose
I made a few changes. Can you show this during the meeting.
Also can Marie or you have the Tables of Results that Marie had done - ie I have attached – I think if there are questions we should show these
Thanks
I'm here and ready
Neil

SUPPORT Outcomes: Ventilation Arm

Outcome	CPAP (N=663)	Surfactant (N=653)	Adjusted P-value
Death in hospital	16% (109/663)	20% (128/653)	0.126
Death @36wks PMA	14% (94/663)	17% (114/653)	0.089
BPD (Phys Def) or Death @36wks	48% (317/663)	51% (333/653)	0.304
BPD (Oxygen) or Death @36 wks	49% (322/663)	54% (353/653)	0.062

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Ventilation Arm Outcomes by GA

GA 24-25 weeks	CPAP (N=285)	Surfactant (N=280)	Adjusted P-value
Death in hospital	24% (68/285)	32% (90/280)	0.034

GA 26-27 weeks	CPAP (N=378)	Surfactant (N=373)	Adjusted P-value
Death in hospital	11% (41/378)	10% (38/373)	0.797

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

SUPPORT Conclusions: Ventilation Arm

- ELBW infants between 24 and 27 6/7ths weeks gestation at birth treated with CPAP and a protocol limited ventilator strategy compared with the use of surfactant within 1 hour of birth and conventional mechanical ventilation have a lower incidence of death or survival with BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse neonatal outcomes.
- Early CPAP with a permissive ventilator strategy is associated with a significant reduction in mortality in the most immature infants.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

SUPPORT Outcomes: SpO2 Arm

Outcome	Low SpO2 (N=654)	High SpO2 (N=662)	Adjusted P-value
Death in hospital	20% (130/654)	16% (107/662)	0.041
ROP	9% (43/483)	18% (95/514)	<0.001
ROP or Death in hospital	28% (171/605)	32% (198/616)	0.205

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

SUPPORT Conclusions: SpO2 Arm

- In the current trial, lower oxygen saturation targeting (actual 85-89%) resulted in a 4% increased mortality and a decrease in Threshold ROP of 9%.
- It is interesting and worrisome that the combined risk difference observed in the trials from the1950s using restricted oxygen was a 4.9% increase in mortality in the oxygen restricted group, which is very similar to the 4% mortality seen in our lower targeted SpO2.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Table 3. BPD outcomes for CPAP vs. Surfactant

Characteristic	CPAP (N=663)	Surfactant (N=653)	Relative Risk for CPAP vs. Surfactant (95% CI)
Death at any time while hospitalized	16% (109/663)	20% (128/653)	0.84 (0.67, 1.05)
Death by 36 weeks PMA	14% (94/663)	17% (114/653)	0.81 (0.63, 1.03)
BPD (physiologic definition)	39% (223/569)	41% (219/539)	0.99 (0.87, 1.14)
BPD (physiologic definition) or death by 36 weeks PMA	48% (317/663)	51% (333/653)	0.95 (0.85, 1.05)
BPD (supplemental O2)	40% (228/569)	44% (239/539)	0.93 (0.82, 1.06)
BPD (supplemental O2) or death by 36 weeks PMA	49% (322/663)	54% (353/653)	0.91 (0.82, 1)
ROP	14% (70/517)	14% (68/480)	0.95 (0.7, 1.28)
ROP or death	28% (176/620)	32% (193/601)	0.87 (0.74, 1.03)

Relative risks are adjusted for GA stratification, center and familial clustering.
Centers with fewer than 10 infants enrolled and those with an incidence of zero for the outcome in question were combined with the geographically closest site for RR calculation.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Table 3. BPD outcomes for CPAP vs. Surfactant
Where GA is 24-25 weeks

Characteristic	CPAP (N=285)	Surfactant (N=280)	Relative Risk for CPAP vs. Surfactant (95% CI)
Death at any time while hospitalized	24% (68/285)	32% (90/280)	0.74 (0.57, 0.98)
Death by 36 weeks PMA	20% (57/285)	29% (82/280)	0.68 (0.5, 0.92)
BPD (physiologic definition)	55% (125/228)	55% (108/198)	1.06 (0.91, 1.25)
BPD (physiologic definition) or death by 36 weeks PMA	64% (182/285)	68% (190/280)	0.96 (0.85, 1.07)
BPD (supplemental O2)	54% (122/228)	54% (106/198)	1.05 (0.9, 1.23)
BPD (supplemental O2) or death by 36 weeks PMA	63% (179/285)	67% (188/280)	0.95 (0.84, 1.06)
ROP	23% (47/202)	31% (55/175)	0.75 (0.54, 1.05)
ROP or death	42% (112/266)	55% (144/261)	0.74 (0.62, 0.89)

Relative risks are adjusted for GA stratification, center and familial clustering.
Centers with fewer than 10 infants enrolled and those with an incidence of zero for the outcome in question were combined with the geographically closest site for RR calculation.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Table 3. BPD outcomes for CPAP vs. Surfactant
Where GA is 26-27 weeks

Characteristic	CPAP (N=378)	Surfactant (N=373)	Relative Risk for CPAP vs. Surfactant (95% CI)
Death at any time while hospitalized	11% (41/378)	10% (38/373)	1.06 (0.7, 1.6)
Death by 36 weeks PMA	10% (37/378)	9% (32/373)	1.12 (0.72, 1.75)
BPD (physiologic definition)	29% (98/341)	33% (111/341)	0.92 (0.74, 1.15)
BPD (physiologic definition) or death by 36 weeks PMA	36% (135/378)	38% (143/373)	0.94 (0.78, 1.13)
BPD (supplemental O2)	31% (106/341)	39% (133/341)	0.83 (0.68, 1.01)
BPD (supplemental O2) or death by 36 weeks PMA	38% (143/378)	44% (165/373)	0.87 (0.73, 1.03)
ROP	7% (23/315)	4% (13/305)	1.86 (0.94, 3.67)
ROP or death	18% (64/354)	14% (49/340)	1.25 (0.88, 1.77)

Relative risks are adjusted for GA stratification, center and familial clustering.
Centers with fewer than 10 infants enrolled and those with an incidence of zero for the outcome in question were combined with the geographically closest site for RR calculation.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Table 1 Patient Description for CPAP vs. Surfactant

Variable	Category	CPAP (N=663)	Surfactant (N=653)	Unadjusted P-value
GA (weeks)	24-25	43% (285/663)	43% (280/653)	0.9686
	26-27	57% (378/663)	57% (373/653)	
Male		52% (342/663)	57% (370/653)	0.0646
Race/ethnicity	Non-Hispanic Black	38% (254/663)	36% (235/653)	0.3681
	Non-Hispanic White	38% (250/663)	42% (271/653)	
	Hispanic	21% (138/663)	19% (121/653)	
	Other/unknown	3% (21/663)	4% (26/653)	
Birth weight (grams)	Mean (n=1316)	834.6 ± 188.2	825.5 ± 198.1	0.3962
Gestational age at birth (weeks)	Mean (n=1316)	26.2 ± 1.1	26.2 ± 1.1	0.6463
Apgar at 1 minute <3		23% (154/661)	26% (167/653)	0.3370
Apgar at 5 minutes <3		4% (26/663)	5% (32/653)	0.3870
PPV in the DR (SUPP03)		66% (435/662)	93% (606/652)	<0.0001*
CPAP in the DR (SUPP03)		81% (538/663)	22% (146/653)	<0.0001*
Intubated in DR (SUPP03)		34% (227/660)	93% (609/652)	<0.0001*
DR intubation for resuscitation		33% (215/660)	27% (176/652)	0.0271*
Surfactant in DR (SUPP03)		14% (93/660)	51% (335/652)	<0.0001*
Surfactant in DR or NICU (SUPP03, SUPP04)		67% (443/660)	99% (646/653)	<0.0001*
Chest compressions in DR (SUPP03)		5% (36/660)	6% (40/653)	0.6026
Epinephrine in DR (SUPP03)		2% (13/660)	4% (27/653)	0.0225*
Antenatal steroids (any)		97% (642/663)	96% (623/652)	0.2248
Antenatal steroids (full course)		74% (486/660)	70% (453/649)	0.1232
Death in the DR (SUPP03/SUPP04)		0% (1/663)	1% (5/653)	0.0978

Table 2: Other outcomes for CPAP vs. Surfactant

Characteristic	Category	CPAP (N=663)	Surfactant (N=653)	Unadjusted P-value
Death in the first week		6% (40/663)	6% (39/653)	0.9630
Total LOS any hospital (survivors only) (NG03, NG05)	Mean (n=1075)	100.4 ± 42.9	101.4 ± 41.6	0.7047
LOS in NRN hospital (survivors only) (NG03, NG05)	Mean (n=1079)	97.7 ± 43.4	97.0 ± 41.6	0.7883
Days on supplemental oxygen (survivors to NG03 status only) (NG07)	Mean (n=1098)	55.0 ± 37.8	58.5 ± 37.6	0.1229
Days on mechanical vent (HFV & CV) (survivors to NG03 status only) (NG07)	Mean (n=1098)	20.0 ± 23.9	23.2 ± 26.2	0.0331*
DOL of last supplemental oxygen through 36 weeks PMA (survivors to NG03 status only) (SUPP05, SUPP11)	Mean (n=1082)	53.6 ± 21.7	55.1 ± 20.3	0.2346
Days on CPAP (survivors to NG03 status only) (NG07)	Mean (n=1098)	16.1 ± 13.1	15.8 ± 14.7	0.7516
Days on nasal SIMV (survivors to NG03 status only) (NG07)	Mean (n=1098)	3.5 ± 6.9	3.6 ± 7.1	0.7239
Discharge on oxygen (NG03 or NG05)		22% (122/550)	24% (124/519)	0.5067
Alive and off MV (HFV/CV) at 7 days (NG07 or SUPP05)		55% (362/655)	49% (318/652)	0.0188*
Pneumothorax (NG03 or SUPP08)		8% (54/663)	6% (36/653)	0.0586
Any air leak in first 14 days (SUPP08)		7% (45/663)	7% (48/653)	0.6901
Medical or surgical NEC (NG03)		13% (83/654)	10% (63/636)	0.1144
PDA requiring surgery (NG03)		11% (73/653)	11% (68/636)	0.7793
IVH grade 3-4 (NG03)		14% (92/642)	11% (72/628)	0.1279
PVL (NG03 or MRI01)		4% (28/643)	4% (26/629)	0.8450
Death or PVL (NG03 or MRI01)		20% (134/663)	23% (147/653)	0.3086
Postnatal steroids for BPD (NG03)		7% (47/649)	13% (83/631)	0.0005*
Postnatal steroids after DOL 21 (SUPP09)		17% (114/659)	23% (149/652)	0.012*
Intubated in DR (SUPP03)		34% (227/660)	93% (609/652)	<0.0001*
Intubated in DR or NICU in first 14 days (SUPP03, SUPP04)		77% (508/661)	100% (649/652)	<0.0001*
Any intubation (SUPP03, SUPP04, SUPP05, SUPP05a, SUPP07)		83% (551/663)	100% (651/653)	<0.0001*

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

SUPPORT Outcomes: Ventilation Arm

Outcome	CPAP (N=663)	Surfactant (N=653)	Adjusted P-value
Death in hospital	16% (109/663)	20% (128/653)	0.126
Death @36wks PMA	14% (94/663)	17% (114/653)	0.089
BPD (Phys Def) or Death @36wks	48% (317/663)	51% (333/653)	0.304
BPD (Oxygen) or Death @36 wks	49% (322/663)	54% (353/653)	0.062

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Ventilation Arm Outcomes by GA

GA 24-25 weeks	CPAP (N=285)	Surfactant (N=280)	Adjusted P-value
Death in hospital	24% (68/285)	32% (90/280)	0.034

GA 26-27 weeks	CPAP (N=378)	Surfactant (N=373)	Adjusted P-value
Death in hospital	11% (41/378)	10% (38/373)	0.797

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

SUPPORT Conclusions: Ventilation Arm

- ELBW infants between 24 and 27 6/7ths weeks gestation at birth treated with CPAP and a permissive ventilator strategy compared with the use of surfactant within 1 hour of birth and conventional mechanical ventilation have a decreased incidence of death or survival with BPD based on the need for oxygen at 36 weeks PMA with no demonstrable increase in any adverse neonatal outcomes.
- Early CPAP with a permissive ventilator strategy is associated with a significant reduction in mortality in the most immature infants.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

SUPPORT Outcomes: SpO2 Arm

Outcome	Low SpO2 (N=654)	High SpO2 (N=662)	Adjusted P-value
Death in hospital	20% (130/654)	16% (107/662)	0.041
ROP	9% (43/483)	18% (95/514)	<0.001
ROP or Death in hospital	28% (171/605)	32% (198/616)	0.205

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

SUPPORT Conclusions: SpO2 Arm

- In the current trial, lower oxygen saturation targeting (actual 85-89%) resulted in an increased risk of mortality.
- It is interesting and worrisome that the combined risk difference observed in the trials from the1950s was a 4.9% increase in mortality in the oxygen restricted group, which is very similar to the 4% mortality increase in the lower targeted SpO2 group that was observed in our trial.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Marie
Any idea why we have more missing outcomes in the Hi SpO2 Group?
In addition are we going to run analyses making assumptions that all the missing data either did have or did not have ROP? I assume that we will need to do this especially as the lower SpO2 group with more death has less ROP without such an adjustment - The missing infants are about 20% of the total
It is again interesting that BPD by oxygen is significantly affected whereas the Physiologic is not - consistent.
Lots to think about. I will wait for the SURF-CPAP data
I will talk to you tomorrow - I am on service but will ensure that I am available - I also have [redacted] but I think these results are even a bigger pain
Be well and Thanks
Neil

Yes, ROP/death is as specified in the protocol: threshold ROP or need for surgery (I included Avastin) vs. mature eyes or two exams with vessels in zone III. Death is death while hospitalized.

Thanks Marie
Can you insert all the p values as adjusted only - I see no point to having unadjusted anywhere as we say in the methods that we will do such adjustments
If you have time please make these changes and remove all the remaining comments - yours I think, and then circulate to the subcommittee for our meeting- It makes for easier reading if all the changes are accepted.
Thanks
Neil

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of consenting parents of 24 0/7ths weeks to 27 6/7ths weeks by best obstetrical estimate within 2 prospective strata, 24 to 25 6/7ths weeks and 26 to 27 6/7th weeks. Infants were randomized to CPAP or surfactant; those randomized to CPAP had CPAP initiated in the delivery room and were subsequently treated using a permissive strategy allowing higher PaCO2s and extubation at higher ventilator settings and infants randomized to surfactant were intubated and received surfactant within 60 min minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while in the NICU and receiving supplemental oxygen, a low target range of 85% to 89% and a high target range of 91% to 95% using specifically altered blinded oximeters.

Results: The study enrolled 1316 infants from January 1 2004 to March 1 2009. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants, and surfactant was given to 14% of the CPAP versus 51% of the surfactant group in the delivery room (all p<0.001), and 67% of the CPAP infants received surfactant in either the delivery room or NICU. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post conceptional age was 49% in the CPAP group versus 54% in the surfactant group, (RR 0.91, 95% CI 0.82, 1.00, when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the infants in the Surfactant arm, (24% vs 32%, RR 0.74, 95% CI 0.57, 0.98). There were no significant differences overall for death in the delivery room nor any differences in length of stay, or days of oxygen for survivors, or discharge on oxygen. More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.019) and fewer required post natal steroids for BPD, (p<.001). All infants in the Surfactant arm were intubated, compared with only ~~83~~77% of the CPAP infants requiring intubation during their nursery course, (p<0.001). There were no significant differences between the groups for air leaks including pneumothoraces.

Conclusions: The use of early CPAP with a permissive ventilator strategy results in a decrease in death or BPD defined as the need for oxygen at 36 weeks post conceptional age compared with the use of surfactant within 1 hour of birth and a conventional mechanical ventilation approach. There were no increased adverse outcomes in the CPAP group, and the surviving infants will be followed for a complete neurodevelopmental assessment at 18 to 22 months. Early CPAP and the use of a permissive ventilator strategy is an evidence based approach for the initial respiratory support of the ELBW infant.

Introduction:

At the present time, there is no agreement as to the optimal approach to respiratory support for the extremely low birth weight (ELBW) infant following delivery. Positive End Expiratory Pressure (PEEP) has been shown to be of benefit in maintaining functional residual capacity (FRC), and continuous positive airway pressure appears beneficial during cardiopulmonary resuscitation[1]. Gregory et al in 1971 first demonstrated that the use of CPAP started at approximately 5.9 hours (+12.4hrs) for their infants < 1500 gm at birth, improved oxygenation[2] in newborn infants with respiratory distress; these observations were followed by prospective studies that demonstrated improved survival in premature infants treated with early CPAP[3]. A review of prospective studies evaluating early (not delivery room) CPAP in the pre-surfactant, pre-antenatal steroid era found that early CPAP improved survival overall and for infants greater than 1500 gm, and was associated with increased pneumothoraces.[4] A more recent review of prophylactic CPAP started in the delivery room reviewed only 2 available trials and found no significant difference between the CPAP and conventionally managed infants and noted a trend to increased adverse outcomes for the CPAP treated infants.[5]

There is substantial retrospective evidence suggesting a benefit for early CPAP in experiences from both the US and other countries.[67] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following the initiation of early CPAP treatment.[8910]

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[1112] Overall surfactant has not been reported to significantly reduce BPD, but may do so

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI). [13]

The recent COIN trial randomized 610 infants from 25 weeks 0 days to 28 weeks 6 days gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[14] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analyses[44], and a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with no difference in death or BPD at 36 weeks.

Field Code Changed

Formatted: Font: 12 pt, Superscript

In view of the current interest in the use of early CPAP and the lack of prospective comparisons of this approach with the evidence based intervention of prophylactic or early surfactant, the SUPPORT study was designed to compare these approaches for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design, and the results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network. This report describes the prospective comparison of CPAP and a permissive ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters. These results will be separately reported.

The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a permissive ventilatory strategy in infants of 24 to 28 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born at a randomizing center, for which a decision had been made to provide full resuscitation, without known malformations, and for whom parental consent had been obtained. The infants were randomized within each center to 2 gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used at all sites for the delivery room administration of CPAP. CPAP or ventilation with PEEP both at a recommended 5 cm H_2O was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU using the T-piece resuscitator or equivalent device and a face mask or nasal prongs. CPAP infants were not to be intubated for surfactant only in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was performed only for the standard NRP indications including failure to respond to positive pressure ventilation (PPV) with evidence of continuing cyanosis or bradycardia, the need for chest compressions, the need to administer intratracheal medications, or other situations in which the resuscitation team determined that surfactant is urgently required.

NICU management: Intubation was performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery. While intubation was never required by protocol, CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean airway pressure (MAP) < 10 cm H2O, ventilator rate < 15 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations CPAP infants were treated using NICU standard of care.

Surfactant Arm: All infants were to be intubated within 1 hour of life and receive surfactant, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30 An FiO2 $\leq$ 35 with a SpO2 > 88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate $\leq$ 15 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and be hemodynamically stable with no evidence of

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard of care.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard of care. For both arms of the trial intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, and thus multiples, were randomized to the same arm of the trial.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, (using the NRN occurrence of death or survival with BPD of 67% using the year 2000 data), and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months (using the NRN occurrence of NDI of 61% using year 2000 data) by 10%. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1312 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the 2 factorial arms.

In addition there was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which required an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks and assigned a diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support. [1516]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each Group who developed their respective outcome measure of survival without BPD at 36 weeks. Adjustment was performed as pre-specified for gestational age stratum, center and familial clustering using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. A two-sided P value of less than 0.05 was considered statistically significant. An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock (O'Brien-Fleming) boundaries were used to develop stopping rules for interim safety and efficacy monitoring. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and a combination of any of the above events.

The study was approved by Human Subjects Committees at all participating sites and RTI, the NRN data center that managed and analyzed all the data, and parental consent for participation in the trial was required before delivery.

Results:

There were 1316 infants enrolled in this trial from Jan 1 2004 through to Mar 1 2009 . The trial was temporarily suspended by the DSMB because of concerns regarding the oximetry data in November 2005 but after a complete review the trial was continued in February 2006 with no protocol changes. The patient descriptive information for the CPAP versus Surfactant arms is shown in Table 1. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. There were no significant differences for sex, birth weight, Apgar scores or race between the 2 treatment groups. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant.

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants, and surfactant was given to 14% of the CPAP versus 51% of the surfactant group; 67% of the CPAP infants received surfactant in the delivery room or NICU, compared to 99% of those in the surfactant group (all p<0.0001). Intubation in the DR occurred in 34% of CPAP infants compared with 93% of surfactant infants, p<0.0001, Table 2.

Comment [MG6]: Unadjusted

Comment [MG7]: Unadjusted

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post conceptional age was significantly lower for the CPAP group compared with the Surfactant group, 49% versus 54%, (RR 0.91, 05% CI 0.82, 1.00, when adjusted for gestational age, center and familial clustering as prespecified). Death during the hospitalization was 4% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata, Table 4. There was a non-significant reduction in the occurrence of BPD using the need for supplemental oxygen, 40% vs 44%, RR 0.93, 95% CI 0.82, 1.06. Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (39% vs 41%, RR 0.99, 95% CI 0.87, 1.14), and a non-significant reduction in the occurrence of death or Physiologic BPD at 36 weeks in the CPAP group, (48% vs 51%, RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room nor any differences in length of stay, or days of oxygen for survivors, or discharge on oxygen. (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.019). There were no significant differences between the groups in air leaks in the first 14 days, pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All infants in the Surfactant arm were intubated, compared with 83% of the CPAP infants who required

Comment [MG8]: If you want oxygen on the day of discharge, that is different and I can get those numbers for you, but what is in the table is discharge on oxygen.

Comment [MG9]: Unadjusted

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

intubation during their nursery course, (p<0.0001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants, 7% vs 13%, p=.0005).

Comment [MG10]: Unadjusted

Comment [MG11]: Unadjusted

Strata Results: 24 – 25 weeks Gestation

Comment [AD12]: Do we need to preface some justification for looking within strata?

There were more non-Hispanic black infants in the CPAP group compared with the Surfactant group. The differences are shown in Table 4 (24-25 wk Strata). CPAP infants had a significantly lower mortality while hospitalized 24% vs 32%, RR=0.74, 95% CI 0.57, 0.98. There was a significantly higher exposure to postnatal steroids for BPD, 20% vs 13%, p=0.02 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata.

Comment [MG13]: We did not do a test comparing this specific category of race/ethnicity, although we could.

Comment [MG14]: Unadjusted

26-27 weeks Gestation

There was no difference in mortality for the CPAP vs Surfactant groups, 10% vs 11%. The CPAP infants required fewer days of oxygen, 40.6 vs 47.1, p=0.01, and lesser days of mechanical ventilation, 11.3 vs 14.9, p=0.01, and fewer infants received postnatal steroids for BPD, 3% vs 8%, p<0.01.

Comment [MG15]: Unadjusted

Comment [MG16]: Unadjusted

Comment [MG17]: Unadjusted

Discussion:

The SUPPORT trial is the first multicenter trial to compare early CPAP with early surfactant given within an hour of life in ELBW infants. The current trial is the largest study reported to prospectively compare the use of early CPAP and early surfactant for the ELBW infant and the only study to include infants of 24 weeks gestation. In a preliminary study we found that 100% of infants of 23 weeks gestation required intubation in the DR, and thus decided that such infants would be unlikely to be successfully treated with CPAP alone following delivery.[17] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[18]

Our study differs from the recently reported COIN trial[14,14] in that we randomized all eligible ELBW infants of consenting families irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP/permissively ventilated infants with infants who all received surfactant within 1 hour of birth. Our method of using early CPAP and a permissive ventilation strategy was a result of previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also utilized a very permissive approach for intubation and the initiation of mechanical ventilation.[6] We believed that testing this complete approach would provide a more relevant result as most units currently using early CPAP also tend to be permissive in their use of intubation.

Our study has demonstrated that early CPAP and a permissive ventilator strategy when compared with surfactant given within 1 hour of birth is associated with a non-significant reduction in death or survival with BPD as defined by the need for oxygen at 36 weeks from 54% to 49% after adjustment for gestational age, center and familial clustering as prespecified, (unadjusted p = 0.046, adjusted p=0.061) We noted however a very significant 8% reduction in death in our 24 to 25 week strata, resulting in a number needed to treat of 12.5 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that this lower incidence of death in these infants along with a reduction of BPD, and significant decreased durations of ventilation, decreased exposure to post natal steroids and a decreased need for intubation in the overall CPAP group represents a substantial clinical benefit compared with the initial use of early surfactant without any observed detrimental effects.

Our rates of BPD are higher than those reported for the COIN trial, 33.9% vs 42.2%, but the difference between the arms is very similar. The higher rates seen in our study no doubt reflect the inclusion of infants of 24 weeks gestation and the lack of inclusion of infants greater than 27 6/7ths weeks, as well as the requirement in the COIN trial that the infants demonstrate adequate spontaneous breathing at 5 minutes of life.

Comment [MG18]: Percent of BPD (by supplemental O2) among our survivors overall

We prospectively identified a number of safety outcomes that we chose to follow as investigators. These included the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks, initially defined as pneumothoraces but later altered to include pulmonary interstitial emphysema, pneumomediastinum and pneumopericardium. We did not find an increase in airleaks with the use of early CPAP at 5 cm H2O compared to the use of early surfactant.

The SUPPORT study was designed as a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we did prospectively agree to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival NDI at 18 to 22 months and these results will be presented after all survivors have been assessed.

Conclusions:

ELBW infants between 24 and 27 6/7ths weeks gestation at birth treated with CPAP and a permissive ventilator strategy compared with the use of surfactant within 1 hour of birth and conventional mechanical ventilation have a decreased incidence of death or survival with BPD

Comment [MG19]: Not significant at p<.05 after adjustment for GA, center, familial clustering

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

based on the need for oxygen at 36 weeks PCA with no demonstrable increase in any adverse neonatal outcomes. Early CPAP with a permissive ventilator strategy is associated with a significant reduction in mortality in the most immature infants, and CPAP treatment was associated with significantly decreased durations of ventilation, exposure to post natal steroids and the need for intubation. Surviving infants will have a complete neurodevelopmental evaluation at 18 to 22 months and these results will be separately reported.

Attached is Table 2 for Wally's paper which now includes the ROP/death outcome. FYI, we have the outcome for 93% of SUPPORT infants. You will note that our N is 1316 - we found out this week that for one of our withdrawn patients we needed to exclude all data (like we did for the patient withdrawn from UCSD).

I will send the CPAP-Surfactant tables soon.

Hello Everyone
I am querying you to determine if we will have enough time to redo all the CPAP-Surf Tables and data with the final data before the meeting on Wednesday. I would like to get the committee's input on that manuscript and get it in final shape. I obviously also want to know when we will see the final ROP data set for the SpO2 paper. These questions are key regarding our agenda on Wednesday.
Please let me know where we are?
We are also awaiting the final data etc to finalize the Consent paper.
I would like to get this into submission as soon as we can
I look forward to hearing from you.
Neil

Table 3. BPD outcomes for CPAP vs. Surfactant
Where GA is 26-27 weeks

Characteristic	CPAP (N=378)	Surfactant (N=373)	Relative Risk for CPAP vs. Surfactant (95% CI)
Death at any time while hospitalized	11% (41/378)	10% (38/373)	1.06 (0.7, 1.6)
Death by 36 weeks PMA	10% (37/378)	9% (32/373)	1.12 (0.72, 1.75)
BPD (physiologic definition)	29% (98/341)	33% (111/341)	0.92 (0.74, 1.15)
BPD (physiologic definition) or death by 36 weeks PMA	36% (135/378)	38% (143/373)	0.94 (0.78, 1.13)
BPD (supplemental O2)	31% (106/341)	39% (133/341)	0.83 (0.68, 1.01)
BPD (supplemental O2) or death by 36 weeks PMA	38% (143/378)	44% (165/373)	0.87 (0.73, 1.03)
ROP	7% (23/315)	4% (13/305)	1.86 (0.94, 3.67)
ROP or death	18% (64/354)	14% (49/340)	1.25 (0.88, 1.77)

Relative risks are adjusted for GA stratification, center and familial clustering.
Centers with fewer than 10 infants enrolled and those with an incidence of zero for the outcome in question were combined with the geographically closest site for RR calculation.

Abstract

Background: The most appropriate initial and ongoing respiratory support for the extremely low birthweight infant (ELBW) has not been established by adequate prospective evidence. The current usual approaches include the early use of continuous positive airway pressure (CPAP) or the early administration of surfactant following endotracheal intubation.

Methods: The SUPPORT study was a randomized multicenter 2 X 2 factorial trial that enrolled preterm infants of consenting parents of 24 0/7ths weeks to 27 6/7ths weeks by best obstetrical estimate within 2 prospective strata, 24 to 25 6/7ths weeks and 26 to 27 6/7th weeks. Infants were randomized to CPAP or surfactant; those randomized to CPAP had CPAP initiated in the delivery room and were subsequently treated using a permissive strategy allowing higher PaCO2s and extubation at higher ventilator settings and infants randomized to surfactant were intubated and received surfactant within 60 min minutes of birth. All infants were also randomized to one of 2 ranges of SpO2 while in the NICU and receiving supplemental oxygen, a low target range of 85% to 89% and a high target range of 91% to 95% using specifically altered blinded oximeters.

Results: The study enrolled 13167 infants from January 1 2004 to March 1 2009. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants, and surfactant was given to 14% of the CPAP versus 51% of the surfactant group in the delivery room (all p<0.001), and 67% of the CPAP infants received surfactant ~~at any time during their hospitalization~~in either the delivery room or NICU~~,~~. The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post conceptional age was 498% in the CPAP group versus 54% in the surfactant group, (~~p< 0.05~~RR 0.91, 95% CI 0.82, 1.00,~~Marie can you please provide the RR and CI~~ when adjusted for gestational age, center and familial clustering). There was a significantly lower mortality during hospitalization in the 24 to 25 weeks strata for the infants in the Surfactant arm, (24% vs 32%, ~~p=0.03~~RR 0.74, 95% CI 0.57, 0.98). There were no significant differences overall for death in the delivery room nor any differences in length of stay, or days of oxygen for survivors, ~~and the~~or ~~need for~~discharge on oxygen ~~at discharge~~. More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.0195) and fewer required post natal steroids for BPD, (p<.00104). All infants in the Surfactant arm were intubated, compared with only 8377% of the CPAP infants requiring intubation during their nursery course, (p<0.001). There were no significant differences between the groups for air leaks including pneumothoraces.

Comment [MG1]: Unadjusted

Comment [AD2]: I would provide the relative risk and 95% CI instead of, or in addition to the p value. Same goes for other CPAP vs surfactant outcome comparisons, both here and in the main text.

Conclusions: The use of early CPAP with a permissive ventilator strategy results in a decrease in death or BPD defined as the need for oxygen at 36 weeks post conceptional age compared with the use of surfactant within 1 hour of birth and a conventional mechanical ventilation approach. There were no increased adverse outcomes in the CPAP group, and the surviving infants will be followed for a complete neurodevelopmental assessment at 18 to 22 months. Early CPAP and the use of a permissive ventilator strategy is an evidence based approach for the initial respiratory support of the ELBW infant.

Introduction:

At the present time, there is no agreement as to the optimal approach to respiratory support for the extremely low birth weight (ELBW) infant following delivery. Positive End Expiratory Pressure (PEEP) has been shown to be of benefit in maintaining functional residual capacity (FRC), and continuous positive airway pressure appears beneficial during cardiopulmonary resuscitation[1]. Gregory et al in 1971 first demonstrated that the use of CPAP started at approximately 5.9 hours (+12.4hrs) for their infants < 1500 gm at birth, improved oxygenation[2] in newborn infants with respiratory distress; these observations were followed by prospective studies that demonstrated improved survival in premature infants treated with early CPAP[3]. A review of prospective studies evaluating early (not delivery room) CPAP in the pre-surfactant, pre-antenatal steroid era found that early CPAP improved survival overall and for infants greater than 1500 gm, and was associated with increased pneumothoraces.[4] A more recent review of prophylactic CPAP started in the delivery room reviewed only 2 available trials and found no significant difference between the CPAP and conventionally managed infants and noted a trend to increased adverse outcomes for the CPAP treated infants.[5]

There is substantial retrospective evidence suggesting a benefit for early CPAP in experiences from both the US and other countries.[67] These reports have documented a decrease in the need for mechanical ventilation among very preterm infants without an increase in morbidity following the initiation of early CPAP treatment.[8910]

The current available evidence demonstrates that prophylactic and early surfactant treatment at less than 2 hours of life significantly decreases mortality, air leak, and BPD in preterm infants.[1112] Overall surfactant has not been reported to significantly reduce BPD, but may do so

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

for the most immature infants and has not been found to significantly reduce subsequent neurodevelopmental impairment (NDI).[13]

The recent COIN trial randomized 610 infants from 25 weeks 0 days to 28 weeks 6 days gestational age at birth, who were able to breathe at 5 minutes of age and had evidence of respiratory distress at that time. Infants were randomized to either intubation and ventilation or CPAP at 8 cm H20. CPAP infants were intubated if they met failure criteria.[14] This study did not compare early CPAP to the early administration of surfactant, and surfactant use followed unit standard of care. There was a significant increase in the occurrence of pneumothoraces in the CPAP group (9.1% vs 3.0%, p=.001), most occurring within the first 2 days, consistent with the findings of an earlier meta analyses[46], and a reduction in death or the need for oxygen at 28 days in the CPAP infants (odds ratio, 0.63; 95% CI, 0.46 to 0.88; P=0.006) with no difference in death or BPD at 36 weeks.

In view of the current interest in the use of early CPAP and the lack of prospective comparisons of this approach with the evidence based intervention of prophylactic or early surfactant, the SUPPORT study was designed to compare these approaches for the most preterm infants. We also randomized infants to 2 ranges of pulse oximetry targets during their exposure to oxygen using a factorial design, and the results for the oximetry study will be reported separately.

Methods

This was a randomized, factorial 2X2 design multi-center trial conducted by the NICHD Neonatal Research Network. This report describes the prospective comparison of CPAP and a permissive ventilatory strategy begun in the delivery room and continuing in the NICU with the early (< 1 hour) intratracheal administration of surfactant followed by conventional mechanical ventilation.

Infants were also randomized to a prospective comparison of a lower SpO2 range (85% to 89%) with a higher more conventional SpO2 range (91% to 95%) until the infant was no longer requiring ventilatory support or oxygen using purpose altered oximeters. These results will be separately reported.

The primary hypothesis of this trial was that relative to infants managed with prophylactic/early surfactant and conventional ventilation that the use of early CPAP and a permissive ventilatory strategy in infants of 24 to 28 weeks gestation with continuing CPAP in the NICU will result in an increased survival without BPD at 36 weeks.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Eligible infants were 24 0/7ths to 27 6/7th weeks at birth by best obstetrical estimate, born at a randomizing center, for which a decision had been made to provide full resuscitation, without known malformations, and for whom parental consent had been obtained. The infants were randomized within each center to 2 gestational age strata, 24 0/7ths to 25 6/7ths weeks, and 26 0/7ths-27 6/7ths weeks.

CPAP Arm - Delivery room management: A T-piece resuscitator, a neonatal ventilator, or an equivalent CPAP methodology was used at all sites for the delivery room administration of CPAP. CPAP or ventilation with PEEP both at a recommended 5 cm H_2O was utilized if the infant required positive pressure during resuscitation. CPAP was continued until admission to the NICU using the T-piece resuscitator or equivalent device and a face mask or nasal prongs. CPAP infants were not to be intubated for surfactant only in the DR, and CPAP infants who required intubation for resuscitation were to receive surfactant within 60 minutes of birth. Intubation for these infants was performed only for the standard NRP indications including failure to respond to positive pressure ventilation (PPV) with evidence of continuing cyanosis or bradycardia, the need for chest compressions, the need to administer intratracheal medications, or other situations in which the resuscitation team determined that surfactant is urgently required.

NICU management: Intubation was performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery. While intubation was never required by protocol, CPAP infants could be intubated if they met any of the following criteria: an FiO_2 >.50 required to maintain an indicated SpO2 $\geq$ 88% for one hour, an arterial $PaCO_2$ > 65 torr documented on a single blood gas, or hemodynamic instability defined as a low blood pressure for gestational age and/or poor perfusion, requiring volume and/or pressor support for a period of 4 hours or more. If intubated within the first 48 hours of life infants were to receive surfactant.

Extubation for CPAP infants was to be attempted within 24 hours if all of the following criteria were met: a PaCO2 < 65 torr with a pH > 7.20, an SpO2 > 88% with an FiO2 < 50%, a mean airway pressure (MAP) < 10 cm H2O, ventilator rate < 15 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and hemodynamically stable, and without a clinically significant patent ductus arteriosus. Re-intubation criteria were the same as those for intubation. After 3 intubations CPAP infants were treated using NICU standard of care.

Surfactant Arm: All infants were to be intubated within 1 hour of life and receive surfactant, followed by continued ventilation. All infants were to be extubated within 24 hours of meeting all of the following criteria: $PaCO_2$ < 50 torr and pH > 7.30 An FiO2 $\leq$ 35 with a SpO2 > 88%, a mean airway pressure (MAP) < 8 cm H_2O, ventilator rate $\leq$ 15 bpm, an amplitude < 2X MAP if on high frequency ventilation (HFV), and be hemodynamically stable with no evidence of

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

clinically significant PDA. Once extubated Surfactant infants were treated using NICU standard of care.

These criteria were in effect for the first 14 days of life, following which the infant was treated as per NICU standard of care. For both arms of the trial intubation could be performed at any time for the occurrence of repetitive apnea requiring bag and mask ventilation, clinical shock, sepsis, and/or the need for surgery.

Randomization was stratified by center and gestational age group, utilizing specially prepared double-sealed envelopes. Deliveries were randomized as a unit, and thus multiples, were randomized to the same arm of the trial.

Hypothesis and sample size: We hypothesized that early CPAP would reduce the incidence of death or survival with BPD at 36 weeks, (using the NRN occurrence of death or survival with BPD of 67% using the year 2000 data), and the occurrence of death or survival with neurodevelopmental impairment (NDI) at 18 to 22 months (using the NRN occurrence of NDI of 61% using year 2000 data) by 10%. We increased the sample size by a factor of 1.12 to allow for multiples to be randomized to the same treatment as this introduced a clustering effect into the design, and increased the sample sizes by a further 17% to adjust for attrition after discharge and before follow-up. This resulted in a sample size of 1312 infants. This sample size was not large enough to determine, with sufficient power, an interaction effect between the 2 factorial arms.

In addition there was a prospective decision to also evaluate the occurrence of BPD using the Physiologic Definition which required an attempt at oxygen withdrawal for infants who required < 30% oxygen at 36 weeks and assigned a diagnosis of BPD to any infant who required more than 30% oxygen at 36 weeks or who required positive pressure support. [1516]

Statistical analyses: Intention-to-treat analyses were performed. The denominator used to calculate the rate of each outcome was the number of infants for whom that outcome was known. The primary analyses focused on the percent of each Group who developed their respective outcome measure of survival without BPD at 36 weeks. Adjustment was performed as pre-specified for gestational age stratum, center and familial clustering using robust Poisson regression implemented in a Generalized Estimating Equation (GEE) model to obtain adjusted relative risks. A two-sided P value of less than 0.05 was considered statistically significant. An independent data safety monitoring committee reviewed the interim safety and efficacy results, including those concerning adverse outcomes, four times. Lan-DeMets spending functions with Pocock (O'Brien-Fleming) boundaries were used to develop stopping rules for interim safety and efficacy monitoring. Safety outcomes monitored included death, pneumothorax, intraventricular hemorrhage and a combination of any of the above events.

The study was approved by Human Subjects Committees at all participating sites and RTI, the NRN data center that managed and analyzed all the data, and parental consent for participation in the trial was required before delivery.

Results:

There were 13167 infants enrolled in this trial from Jan 1 2004 through to Mar 1 2009 . The trial was temporarily suspended by the DSMB because of concerns regarding the oximetry data in November 2005 but after a complete review the trial was continued in February 2006 with no protocol changes. The patient descriptive information for the CPAP versus Surfactant arms is shown in Table 1. There were 565 infants enrolled in the lower gestational age strata, and 751 in the higher strata. Marie can you correct these – we had one additional child and I do not know which arm that infant was in – the Tables need correcting for the actual number as well – they all total 1316 – and we have 1317 There were no significant differences for sex, birth weight, Apgar scores or race between the 2 treatment groups. The Surfactant group received significantly more epinephrine in the delivery room and had a trend for higher DR mortality which was not statistically significant.

In the delivery room, 66% of the CPAP infants received positive pressure ventilation compared with 93% of the surfactant infants, and surfactant was given to 14% of the CPAP versus 51% of the surfactant group; , and 67% of the CPAP infants received surfactant at any time during their hospitalizationin the delivery room or NICU, compared to 99% of those in the surfactant group (all p<0.0001). Intubation in the DR occurred in 34% of CPAP infants compared with 93% of surfactant infants, p<0.0001, Table 2.

Comment [MG7]: Unadjusted
Comment [MG8]: Unadjusted

The primary outcome of death or BPD, defined as the need for supplemental oxygen at 36 weeks post conceptional age was significantly lower for the CPAP group compared with the Surfactant group, 498% versus 54%, (p < 0.05RR 0.91, 05% CI 0.82, 1.00, when adjusted for gestational age, center and familial clustering as prespecified Marie we need the RR etc as Abhik has asked for)). Death during the hospitalization was 4% lower for the CPAP group overall, and was significantly lower in the CPAP arm for the 24 to 25 week strata, Table 4. There was a non-significant reduction in the occurrence of BPD using the need for supplemental oxygen, 40% vs 44%, p=0.27RR 0.93, 95% CI 0.82, 1.06. Using the Physiologic Definition for BPD there was no decrease in the occurrence of BPD in the CPAP group (4039% vs 41%, p=0.96RR 0.99, 95% CI 0.87, 1.14), and a non-significant reduction in the occurrence of death or Physiologic BPD at 36 weeks in the CPAP group, (48% vs 51%, p=0.32RR 0.95, 95% CI 0.85, 1.05).

There were no significant differences overall for death in the delivery room nor any differences in length of stay, or days of oxygen for survivors, and the need for oxygen at dischargeor

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

discharge on oxygen. (Table 3). More CPAP infants were alive and off mechanical ventilation by day 7, (p=0.019). There were no significant differences between the groups in air leaks in the first 14 days, ~~air leaks~~pneumothoraces during the hospital stay, medical or surgical NEC, PDA requiring surgery, or severe IVH. All infants in the Surfactant arm were intubated, compared with 83% of the CPAP infants who required intubation during their nursery course, (p<0.0001). There was a significant reduction in the use of postnatal steroids for BPD in the CPAP infants compared with the Surfactant infants, 7% vs 13%, p=.0005).

Comment [MG9]: If you want oxygen on the day of discharge, that is different and I can get those numbers for you, but what is in the table is discharge on oxygen.

Comment [MG10]: Unadjusted

Strata Results: 24 – 25 weeks Gestation

Comment [AD13]: Do we need to preface some justification for looking within strata?

There were ~~significantly~~ more non-Hispanic black infants in the CPAP group compared with the Surfactant group. The differences are shown in Table 4 (24-25 wk Strata). CPAP infants had a significantly lower mortality while hospitalized 24% vs 32%, ~~p=0.03~~028RR=0.74, 95% CI 0.57, 0.98. There was a significantly higher exposure to postnatal steroids for BPD, 20~~1~~% vs 13%, p=0.02 for the Surfactant group, and there were more infants alive and off mechanical ventilation at 1 week in the CPAP infants in this strata.

Comment [MG14]: We did not do a test comparing this specific category of race/ethnicity, although we could.

Comment [MG15]: Unadjusted

26-27 weeks Gestation

There was no difference in mortality for the CPAP vs Surfactant groups, 10% vs 11%. The CPAP infants required fewer days of oxygen, ~~36.8~~40.6 vs ~~46.5~~47.1, p=<0.01, and lesser days of mechanical ventilation, ~~10.7~~11.3 vs 14.9~~2~~, p=<0.01, and ~~less~~ fewer infants received postnatal steroids for BPD, 3% vs 8%, p<0.01.

Comment [MG16]: Unadjusted

Discussion:

The SUPPORT trial is the first multicenter trial to compare early CPAP with early surfactant given within an hour of life in ELBW infants. The current trial is the largest study reported to prospectively compare the use of early CPAP and early surfactant for the ELBW infant and the only study to include infants of 24 weeks gestation. In a preliminary study we found that 100% of infants of 23 weeks gestation required intubation in the DR, and thus decided that such infants would be unlikely to be successfully treated with CPAP alone following delivery.[17] Others have retrospectively reported that some of these infants can be successfully managed with early CPAP, but the majority of such infants require intubation.[18]

Our study differs from the recently reported COIN trial[~~14~~14] in that we randomized all eligible ELBW infants of consenting families irrespective of whether they demonstrated spontaneous breathing, included infants of 24 weeks gestation and compared the CPAP/permissively ventilated infants with infants who all received surfactant within 1 hour of birth. Our method of using early CPAP and a permissive ventilation strategy was a result of previous retrospective reviews of practice which demonstrated that the unit with the most success using CPAP also

Field Code Changed

utilized a very permissive approach for intubation and the initiation of mechanical ventilation. Error! Bookmark not defined.[8] We believed that testing this complete approach would provide a more relevant result as most units currently using early CPAP also tend to be permissive in their use of intubation.

Our study has demonstrated that early CPAP and a permissive ventilator strategy when compared with surfactant given within 1 hour of birth is associated with a significant reduction in death or survival with BPD as defined by the need for oxygen at 36 weeks from 54% to 498%. We also noted a very significant 8% reduction in death in our 24 to 25 week strata, resulting in a number needed to treat of 12.5 for each additional survivor. The group of 565 infants in our 24 to 25 week strata to our knowledge represents the largest prospective group of such immature infants to be randomized in any neonatal trial evaluating respiratory interventions. We believe that this lower incidence of death in these infants along with a reduction of BPD and decreased durations of ventilation and exposure to post natal steroids in the overall CPAP group represents a substantial clinical benefit compared with the initial use of early surfactant.

Comment [MG19]: Adjusted p-value is 0.0621, Unadjusted is 0.0463

Our rates of BPD are higher than those reported for the COIN trial, 33.9% vs ~~38.9~~42.2%, but the difference between the arms is very similar. The higher rates seen in our study no doubt reflect the inclusion of infants of 24 weeks gestation and the lack of inclusion of infants greater than 27 6/7ths weeks, as well as the requirement in the COIN trial that the infants demonstrate adequate spontaneous breathing at 5 minutes of life.

Comment [MG20]: Percent of BPD (by supplemental O2) among our survivors overall

We prospectively identified a number of safety outcomes that we chose to follow as investigators. These included the need for compressions in the delivery room, the occurrence of severe IVH, and the incidence of airleaks, initially defined as pneumothoraces but later altered to include pulmonary interstitial emphysema, pneumomediastinum and pneumopericardium. We did not find an increase in airleaks with the use of early CPAP at 5 cm H2O compared to the use of early surfactant.

The SUPPORT study was designed as a factorial design with each infant randomly receiving 2 interventions, CPAP vs Surfactant, and a lower versus higher SpO2 target range. While the study was not powered to detect an interaction between the 2 interventions, we did prospectively agree to evaluate such interactions and none were found. Both arms of the study were adequately powered for both the outcomes at neonatal discharge and the occurrence of survival NDI at 18 to 22 months and these results will be presented after all survivors have been assessed.

Conclusions:

ELBW infants between 24 and 27 6/7ths weeks gestation at birth treated with CPAP and a permissive ventilator strategy compared with the use of surfactant within 1 hour of birth and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

conventional mechanical ventilation have a decreased incidence of death or survival with BPD based on the need for oxygen at 36 weeks PCA with no demonstrable increase in any adverse neonatal outcomes. Early CPAP with a permissive ventilator strategy is associated with a significant reduction in mortality in the most immature infants. Surviving infants will have a complete neurodevelopmental evaluation at 18 to 22 months and these results will be separately reported.

Comment [MG21]: Not significant at p<.05 after adjustment for GA, center, familial clustering

Okay, I will make the changes. For the ROP correction on the last exam the infant received in the hospital he met threshold criteria in both eyes and we reviewed his medical records and it was not stated in the hospital chart as threshold being met but according to the MOP he met criteria so we marked yes for threshold for both eyes for the last in hospital exam.

Thanks, Ruth. Just to clarify, according to the randomization number entered on the SUPP02, it looks like the infant was assigned to blue and that the orange oximeter was placed in error. The reason you received the query is that the treatment assignment entered on the SUPP02 should match what the

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

infant was assigned to per the randomization card (blue) rather than what they actually received. Currently, the oximeter assignment entered is orange, not blue. So, that still needs to be changed in the DMS.

What did you edit to resolve the ROP query?

Thanks for all your help!

Marie

Yes, we had a protocol violation entered for that baby already in the system because the baby was randomized to orange and was placed initially on a blue Oximeter and when the error was identified we corrected it by putting the infant on the correct monitor and completing a protocol violation. I noticed when we created the protocol violation form the reason was selected as 10 and it should have been 99 (other) and a comment included stating what the violation was.

I corrected this on the protocol violation form by going in an editing the form to select 99.

Kim,

I have a question for you regarding ROP data for one of your infants. For infant (b) (6) on exam dated 5/27/08, both eyes are coded as having vessels in zone III with stage 2 ROP and plus disease. According to Dale Phelps, ROP in zone III is not associated with plus disease, so I'm wondering if either the plus disease or the zone might have been entered in error? The reason for my concern is that if the zone was actually II then the infant met criteria for threshold ROP and would have a negative outcome instead of a positive one. We're trying to finalize the ROP outcome, so if you could check into that for me and let me know as soon as possible what the result is I would really appreciate it. Thank you so much!

Date: Monday, October 26, 2009 10:46:00 AM

Hi all,

As Rose indicates, the NG03 collects information about physical conditions rather than IVH grade to improve consistency across centers. For this reason, we will apply the NRN criteria for the IVH grades to the data entered on NG03 and this will take precedent over the grade of IVH entered on SUPP09. Thanks for your help in clarifying the situation with this infant.

Please use definitions from the manual in reporting this one. We ask for descriptors

b. Date of sonogram with most severe findings:	__ __ / __ __ / __ __ __ __ Month Day Year					
c. Blood/echo-density in germinal matrix/sub-ependymal area?	Y	N				
	(1) RIGHT		(2) LEFT			
d. Blood/echo-density in the ventricle?	Y	N			Y	N
e. Ventricular size enlarged with concurrent	Y	N			Y	N

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

or prior blood in the ventricles?				
f. Ventricular size enlarged without concurrent or prior blood in the ventricles?	Y	N	Y	N
g. Blood/echo-density in the parenchyma?	Y	N	Y	N

We no longer ask the sites to "grade the IVH" for this very reason!!!

Hi all...here's the dilemma:

the radiologist called the first head ultrasound result a grade II, but the report mentions ventricular dilatation....but again the summary statement is grade II...I'd call a grade II on both crf's (if it hasn't been alreaady)...the repeat head ultrasound from the next day says: "unchanged mild ventriculomegaly" and continues in the summary calling it a grade II.

the ngo3 asks about dilatation....but here we have a radiologist calling dilatation, classifying a grade II, and then saying 'mild dilatation' the next day.....and the baby ultimately resolved....i think sticking w/ the lower acuity classification, and saying they called dilatation, but it was mild.....would be ok....but will take suggestions from others...

GOldberg" <goldb008@mc.duke.edu>, "Das, Abhik" <adas@rti.org>
Subject RE: *****URGENT SUPPORT cross-form queries Center 19 23OCT09

Kim,

The reason we are picking this up as a grade III IVH is because the baby is coded on NG03 as having "ventricular size enlarged with concurrent or prior blood in the ventricles" on the left side. When there is both blood in the ventricle and the ventricular size is enlarged, that fits our Network definition for grade III. If there was blood in the ventricle without the ventricular size enlarged we classify that as a grade II. Are the data entered on the NG03 accurate?

Thanks for helping us straighten this out.

Rose
It must be in the way we have it coded as this child only has a grade 2. Mike double checked this child from a previous query. I am out of town but will get someone on the phone to resolve this on Monday but here is what we responded to before. The NG03 was incorrectly coded as a grade 3 and I changed the data to reflect Mike's review.

Center ID number=19 Network number=(b) (6) NG02 birth date=(b) (6)

Per NG03 infant had HUS with IVH 3-4 on DOL 7 but severe IVH is not recorded on SUPP09. **Resolution: IVH as incorrectly keyed from the NG03 and IVH 2 that is listed on the SUPP09 is correct. Information has been keyed into DMS and sent to RTI.**			**Resolved**

Thanks
Kim

Subject: more for extended SUPPORT follow-up

Hi Betty and Rose,

In the SUPPORT neuroimaging and neurodevelopmental outcomes cohort, I think we will have one of the few big cohorts with both 18-22 month Bayley III data and school age quantitative IQ data. This is an opportunity for an examination of predictive capability of the Bayley III, other variables associated with good or poor prediction of school age outcome from 18-22 month data, etc. I think it would be useful to put together a formal secondary analysis proposal for this - I would be happy to work on this with Betty. But, I think we should plan on proposing that ALL the follow-up PI's will be authors on any publication that comes out of it. Having all the follow-up PIs as "real" authors (rather than on a boilerplate) could serve as an incentive for both further participation in analyses and publications, and also to make sure that patients are tracked and get in to be seen at school age.

This would be many co-authors, but I think there is probably a precedent for such?

Thanks -

Susan

Subject: RE: NRN Calls- SUPPORT Call

Hi Abbot
I thought your detailed points required some response. You are the only outside person apart from Wally and Abhik that has sent any comments.
I have made changes as per your first suggestions
The manuscript length if we do to NEJM is already at the limit
The issues that you raise however are important
The gender issue is of concern to me but I have been advised by our statistical advisors that as it is not significant and as we did our pre-specified adjustments, that we should not readjust for this.
As for the physiologic definition a large number of children were not challenged and the diagnosis is not at all as clear using this definition, but we committed to report it and will.
I happen to believe that the difference in death in the early gestation strata is the very strongest data to date to support the use of early CPAP – exactly why needs to be further looked into the causes of death do not appear that different and I have always worried about intubation and its negative physiological effects. I know that death was not a pre-specified Primary but it is the most important outcome so I think even the NEJM will not have a problem with us reporting it as we have. The TOBY Trial is a good example of reporting about secondary outcomes. I have tried not to over emphasize but merely state the outcome
We need a separate publication to look at the severity of BPD and longer term outcomes – a repeat of the NRN paper (Ehrenkranz, R. A.; Walsh, M. C.; Vohr, B. R.; Jobe, A. H.; Wright, L. L.; Fanaroff, A. A.; Wrage, L. A., and Poole, K. Validation of the National Institutes of Health consensus definition of bronchopulmonary dysplasia. Pediatrics. 2005 Dec; 116(6):1353-60; ISSN: 1098-4275
The SUPPORT trial will be stronger evidence as it is all from a prospective trial etc. Here we can discuss various levels of severity including the need for CPAP/Vent at 36 weeks. This paper would be a great place to go into detail about the Physiologic definition- Maybe you and Michelle should write this.
I did not want to have the current paper try to cover too much ground and would like to see a quick publication because I think it is important as is the SpO2 paper.
Anyway, I very much appreciate your input.
Be well
Neil

Cc: WCarlo@PEDS.UAB.edu; HigginsR@mail.nih.gov
Subject: RE: NRN Calls- SUPPORT Call

Neil
Excellant start to a seminal paper. I have a few comments:
1) I think there should be a clear statement of hypothesis in the abstract and in the introduction; Right now it appears in the Methods.
2) Methods
a. Antenatal consent is buried at the end and may be better placed earlier in the description of how we got this done in the DR.
b. Second paragraph of the description of the surfactant arm it is stated that intubation for either group could be performed at any time for a series of indications. However when the surfactant group has been extubated they are cared for per the standards of the NICU so this may confuse some readers. Could remedy this by amending the last sentence of the preceding paragraph as follows:
"Once extubated surfactant infants were treated using NICU standard of care *including indications for re-intbutaion*."
c. Safety outcomes monitored: do we want to add CPR in the DR?
d. Should you state the guidelines for post-natal steroid use?
3) Results:
a. No signficant differences in sex; seems like a trend toward a difference inspite of randomization
b. Will there be a table for the primary outcome?
c. Should there be a statement regarding extent of compliance with the protocol.
4) Discussion:
a. Should the trend in gender differences be discussed re our outcomes
b. I think you will need to spend more space discussing the issue of differences in BPD when using oxygen use vs the physiologic O2 challenge. Some will look at this as minimizing the extent of differences reported so best to place the two observations in perspective.
c. Differences in deaths for the lower strata: can we categorize the time of death and maybe associated morbidites for the infants that died within each group strata?
d. Will differences in severity of BPD between groups be a subject of another manuscript? Some will have difficulty in putting these observations in their proper place withtout that altougth the death results I would assume would weigh quite heavily with readers.
Hope this helps, Tx, AL

Subject: NICHD NRN SUPPORT TRIAL ROP data adjudication conference call

Dear all,

We will have the NICHD NRN SUPPORT Trial data lock on 10/20/09 and would like to ask that you be part of an adjudication committee to determine acute final ROP status (if possible) for cases that are not straight forward. We would like to have this conference call on **Friday, October 23, 2009 from 3:00 = 5:00PM (EST).** We would be sending the data for case reviews on 10/22/09. Currently, there are about 50 cases where the infant had one exam in zone 3 (instead of the two consecutive exams required to meet our final status requirement) and about 50 who only had exams in zone 2. The study subcommittee may determine these later cases are classified as undetermined per the study manual definition but after data lock we will have a better idea of cases needing review. I have attached the study manual for reference.

Please let me know if you are willing and available this date and time.
Thanks,
Kris

Dale:

These documents are meant to provide you relevant information that helps adjudicate the ROP status for these babies, so that we can potentially assign a primary outcome to at least some of them. The committee can decide how best to use this information. My thought is that while the adjudication would be a collective process that can only happen at the meeting itself, considering that there are 97 infants to adjudicate and the meeting is only scheduled for an hour, perhaps the committee members can consider coming to some preliminary judgments beforehand. Then the meeting can go over only those cases where there is initial disagreement among the members.

Thanks

Abhik

Subject: RE: NICHD NRN SUPPORT TRIAL ROP Adjudication Process conference call

Please clarify what we should do with these documents. I think we are just to familiarize ourselves with what we have at this point, but not to try and do any judgments for the call.

Is this correct?

Dale

Attached are the following documents for the ROP adjudication call.

1) ROP adjudication data - ROP status unknown 21OCT09.pdf - This document contains data from ROP exams (form SUPP10) and 18 Month Follow-up (form NF05) for the 97 infants who survived to discharge and are missing the final ROP outcome.
2) MOP instructions for ROP data.pdf - This document contains instructions for completing the SUPP10 and vision-related items on NF05 from the SUPPORT and Follow-up Manuals of Operations.
3) Copies of SUPP10 and NF05 for reference.

Please let me know if you have any questions.

Thanks,
Marie

Subject: RE: NICHD NRN SUPPORT TRIAL ROP Adjudication Process conference call

Dear all,

We have scheduled a conference call for Friday, October 23, 2009 from 4:00 = 5:00PM (EST) to discuss a process to adjudicate cases with unclear ROP outcome. Contacts below:

Call in number: 1-866-675(b) (6)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Pass code: (b) (6) (the "#" sign at the end is required)

Thanks,
Kris

Subject: NICHD NRN SUPPORT TRIAL ROP data adjudication conference call

Dear all,

We will have the NICHD NRN SUPPORT Trial data lock on 10/20/09 and would like to ask that you be part of an adjudication committee to determine acute final ROP status (if possible) for cases that are not straight forward. We would like to have this conference call on Friday, October 23, 2009 from 3:00 = 5:00PM (EST). We would be sending the data for case reviews on 10/22/09. Currently, there are about 50 cases where the infant had one exam in zone 3 (instead of the two consecutive exams required to meet our final status requirement) and about 50 who only had exams in zone 2. The study subcommittee may determine these later cases are classified as undetermined per the study manual definition but after data lock we will have a better idea of cases needing review. I have attached the study manual for reference.

Please let me know if you are willing and available this date and time.
Thanks,
Kris

Hi Rose and Neil,

Attached is the School Age Breathing Outcomes Proposal, a secondary to SUPPORT, along with a symptom questionnaire (modified ISAAC questionnaire) and summary of the interest /resource survey that we circulated over the summer. Richard and I feel it is ready for review by the protocol committee. If you agree, can you forward to the protocol committee?

Thanks

Tim

Synopsis: For SUPPORT– Breathing Outcomes Study (SUPPORT-BOS) patients, we propose to extend pulmonary follow-up to perform pulmonary function testing at 6-7 years of age. Longer term, longitudinal pulmonary follow up of SUPPORT patients will provide important data on three critical outcomes of the Trial, 1) do the SUPPORT Trial interventions, management with high vs. low oxygen saturation targets and early CPAP vs. prophylactic surfactant and ventilation, result in improved lung function, reduced respiratory symptoms and less need for pulmonary care at 6-7 years of age; 2) do the pulmonary benefits of SUPPORT reduce reaction or susceptibility to secondary pulmonary insults such as lung irritants, infections and allergens during childhood; and 3) are the pulmonary benefits of SUPPORT observed at 18-22 months of age sustained during childhood. The primary outcome will be comparison of the FEV_1 ratio for infants in each of the four SUPPORT treatment groups at 6-7 years of age. Important secondary outcomes will include forced vital capacity (FVC), forced midexpiratory flow rate (FEV_{25-75}), ratio of FEV1 to FVC (FEV%), peak expiratory flow velocity (PEF) and prevalence of symptomatic airway dysfunction and need for medically attended pulmonary care. By evaluating pulmonary function at school age, the SUPPORT – School Age Breathing Outcomes Study will not only provide valuable data on the long term pulmonary effects of SUPPORT but also provide mechanistic insights into the primary and secondary causes of pulmonary morbidity among preterm infants during childhood.

Specific Aims: The SUPPORT-School Age Breathing Outcomes Study will address 3 specific aims.
Specific Aim #1 – Measure the effect of the SUPPORT primary interventions (management with high vs. low oxygen saturation targets and early CPAP vs. prophylactic surfactant and ventilation) on pulmonary function, respiratory symptoms and need for pulmonary care.

Hypothesis #1a - Relative to infants managed with a higher SpO2 range, infants whose neonatal lung disease was managed with a lower targeted SpO2 range will have less symptomatic airway dysfunction, reduced need for outpatient pulmonary care and improved pulmonary function (greater FEV_1, FEV_{25-75}, forced vital capacity and peak flow velocities) at 6-7 years of age, regardless of whether they developed BPD or not.

Hypothesis #1b - Relative to infants managed with prophylactic surfactant and conventional ventilation, infants whose neonatal lung disease was managed with the early use of CPAP and a permissive ventilator strategy will have less symptomatic airway dysfunction, reduced need for outpatient pulmonary care and improved pulmonary function at 6-7 years of age, regardless of whether they developed BPD or not.

Specific Aim # 2 – Evaluate the effect of neonatal management with high vs. low oxygen saturation targets on the pulmonary response to secondary pulmonary irritants, such as environmental tobacco smoke exposure, inhaled allergens and respiratory infections during childhood by comparing pulmonary function among infants exposed to secondary respiratory irritants by SUPPORT oxygen saturation target assignment.

Hypothesis #2a (A Novel Second Hit Hypothesis)- Among infants who are exposed to post-neonatal (home or outpatient) environmental respiratory irritants such as tobacco smoke, household allergens or acute viral respiratory illnesses requiring hospitalization, infants whose neonatal lung disease was managed with a lower rather than higher targeted SpO2 will have less symptomatic airway dysfunction, reduced need for outpatient pulmonary care and improved pulmonary function at 6-7 years of age, regardless of whether they developed BPD or not.

Hypothesis #2b (A Novel Second Hit Hypothesis)- Among infants who are exposed to post-neonatal (home or outpatient) environmental respiratory irritants such as tobacco smoke, household allergens or acute viral respiratory illnesses requiring hospitalization, whose neonatal lung disease was managed with the early use of CPAP and a permissive ventilator strategy will have less symptomatic airway dysfunction, reduced need for outpatient pulmonary care and improved pulmonary function at 6-7 years of age, regardless of whether they developed BPD or not.

Specific Aim #3 – Evaluate the relationship between symptomatic airway dysfunction at 18-22 months of age measured by parental report as part of the Breathing Outcomes Study and respiratory symptoms, need for pulmonary care and pulmonary function at 6-7 years of age. By following individual infants from birth, through 18-22 months and on to 6-7 years of age, this aim will evaluate how pulmonary morbidity, the

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

pulmonary benefits of SUPPORT and the burden of pulmonary care for extremely premature infants evolves over time. This information will be valuable in developing recommendations for pulmonary follow up and care and estimating treatment costs of future extremely preterm infants.

> Hypothesis #3 – BPD and symptomatic airway dysfunction at 18-22 months of age (primary outcome of the Breathing Outcomes Study) better predict respiratory symptoms and need for pulmonary care than abnormal pulmonary function at 6-7 years of age.

Background:

Extremely premature infants are born during a critical juncture in lung development. Perinatal environmental exposures or insults occurring during this time, such as supplemental oxygen and mechanical ventilation, interfere with normal pulmonary development resulting in impaired lung growth, structure and function. Although infants who develop BPD are at greatest risk, respiratory symptoms and need for pulmonary treatment are a significant morbidity for many preterm children. Longitudinal studies in term infants suggest that the origins of wheezing and asthma may begin in early life when genetically susceptible or environmentally sensitized infants are exposed to specific allergens, infectious agents or environmental pollutants (1;2). Premature infants, especially very low birth weight infants (VLBW, <1500 grams, approximately 32 weeks' gestation or less), commonly have respiratory exposures to concentrated oxygen and mechanical ventilation, exposures that are associated with high risk for asthma-like episodes of wheezing. How these neonatal respiratory exposures interact with common allergens, infectious agents or environmental pollutants to cause later pulmonary morbidity for premature infants is not known. Greater understanding of the interaction between neonatal and post-neonatal factors may lead to development of improved methods to avoid secondary lung injury among formerly extremely premature infants and to promote their long-term respiratory health. The potential costs are great. Because mean per capita asthma related costs may be 5 times greater for VLBW than normal weight infants, VLBW infants contribute substantially to the public health burden of wheezing in the United States (3;4).

Absence of Long Term Pulmonary Outcome Studies of Randomized Neonatal Oxygen Exposure

There are no longitudinal pulmonary follow up studies of randomized neonatal oxygen or mechanical ventilation exposure on school age pulmonary outcome. The duration of supplemental oxygen in the neonatal period is an important predictor of pulmonary morbidity. Kennedy et al found that 20 days of oxygen had little effect on FEV1, but each additional week of supplemental oxygen after that time was associated with a progressive reduction in FEV_1 of 3% (5). However, duration of oxygen therapy does not discriminate between oxygen as a cause of lung injury and oxygen as a marker for the severity of lung injury. Whether the level of oxygen exposure in the early neonatal period affects the need for later oxygen to treat lung injury cannot be ascertained from current literature. By randomizing oxygen saturation targets and thereby level of oxygen exposure in the early neonatal period, SUPPORT is the only study with the potential to discriminate between the effect of level of concentrated oxygen as a neonatal lung toxicant and duration of supplemental oxygen as a treatment for chronic lung disease. The SUPPORT – School Age Breathing Outcomes study will provide essential information on how the level of oxygen exposure in the neonatal period affects pulmonary function.

Lack of Longitudinal Pulmonary Outcome Studies for Extremely Premature Infants

Cross sectional pulmonary outcome studies have shown that premature infants have impaired pulmonary function through childhood and into young adulthood (5-11). However, less is known about changes in pulmonary symptoms and lung function in individual patients over time. Available longitudinal pulmonary outcome studies have mostly targeted VLBW infants, a population at less risk for BPD than ELBW infants and therefore likely at less risk for ongoing pulmonary morbidity during childhood (12-14). The SUPPORT – School Age Breathing Outcomes Study will provide important longitudinal data on the natural history of pulmonary morbidity among extremely premature infants and will allow the burden of providing pulmonary care for this population to be quantified.

Neonatal Oxidant Lung Injury May Increase Susceptibility to Later, "Second Hit" Pulmonary Injury

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

For term infants, post-neonatal environmental exposures such as environmental tobacco smoke, household allergens and lung infections exert long-term effects on lung function. For extremely preterm infants, hyperoxia- and mechanical ventilation-associated lung injury exert long-term effects on lung structure and function, potentially adversely affecting aging and respiratory health into adulthood. Little is known about the interplay between early neonatal respiratory exposures, such supplemental oxygen and mechanical ventilation, and later, post-neonatal environmental exposures on respiratory symptoms and lung function during childhood. Data emerging from animal and human studies suggest that neonatal exposure to concentrated oxygen not only causes direct lung injury but also alters how the lung responds to subsequent respiratory exposures such as inhaled lung irritants, allergens and infectious agents that commonly occur during childhood.

Oxygen Exposure Causes Increased Susceptibility to Respiratory Allergens

Studies in mice, rats, guinea pigs and rhesus monkeys suggest that exposure of the term or preterm lung to oxidant stress for relatively brief periods in the neonatal period is sufficient to cause airway remodeling and smooth muscle changes that predispose toward airway narrowing and reactivity to subsequent environmental challenges (15-19). Schlegle exposed infant monkeys to repeated cycles of inhaled House Dust Mite Allergen (HDMA), ozone or filtered air. While repeated exposure to either ozone or HDMA had mild effects, exposure to cycles of ozone followed by HDMA resulted in reduced airway number, hyperplasia of bronchial epithelium, increased mucous cells, alterations in airway smooth muscle, airway hyperreactivity, interrupted postnatal basement membrane zone differentiation and reorganization of the airway vascular and immune system. Using supplemental oxygen rather than the stronger oxidant, ozone, Schulman found that exposure of newborn guinea pigs to 70% oxygen for 96 hours resulted in airway hyper-reactivity at 2 and 9 days after cessation of oxygen. These studies show that exposure of infants to oxidant lung stress during early postnatal lung development sensitizes the lung, favoring increased airway reactivity, greater mucus production and development of intermittent airway obstruction associated with wheeze (20). By evaluating infants exposed to different levels of oxygen in the neonatal period and analyzing their pulmonary function by exposure to later environmental allergens or irritants (wood or tobacco smoke), the SUPPORT – School Age Breathing Outcomes Study may provide important mechanistic insights into the effects of early neonatal oxygen exposure and later reaction environmental allergens.

Neonatal Oxygen Exposure Causes Increased Susceptibility to Later Acute Respiratory Infections

Epidemiologic studies indicate children who have been exposed to concentrated oxygen in the neonatal period for treatment of RDS and/or BPD are more likely to have viral infections and out-of-school sick days than children who were not exposed to oxygen (21-23). Whereas it is well known that hyperoxia permanently disrupts postnatal lung development, less is known about how neonatal hyperoxia affects the lung's response to later exposure to respiratory pathogens and inhaled toxicants. Recently, in an animal model of hyperoxic lung injury, O'Reilly et al. showed that short-term hyperoxia at levels that are not associated with chronic alveolar changes during postnatal lung development significantly increases the sensitivity of adult mice to acute respiratory infection (24). Unlike infected siblings that developed disease and recovered, oxygen-exposed and infected mice showed enhanced recruitment of inflammatory cells into the lung leading to greater alveolar fibrosis and mortality. In unpublished data, neonatal hyperoxia resulted in significant delay in clearing influenza virus, a finding that may also contribute to greater mortality. These studies imply that neonatal hyperoxia disturbs innate immunoregulatory pathways in lung, which may contribute to the increased susceptibility to respiratory viral infections, greater disease severity and possibly reductions in lung function. By evaluating infants exposed to different levels of oxygen in the neonatal period and analyzing their pulmonary function by number of acute respiratory infections requiring hospitalization during the preschool years, the SUPPORT – School Age Breathing Outcomes Study may provide important mechanistic insights into the effects of early oxygen exposure and susceptibility to acute respiratory infections.

Alveolar Simplification Associated with BPD May Predispose Toward Earlier Lung Aging

BPD has changed over time. Whereas "old" BPD was associated with fibrosis, cystic alveolar changes and airway inflammation, "new" BPD is characterized by less airway involvement but significant alveolar simplification. Because normal lungs in healthy adults undergo emphysematous changes during aging,

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

there is concern that premature infants who have suffered alveolar simplification as a result of BPD or extremely preterm birth will have earlier or more rapidly progressive emphysematous changes as they age. A recent study of pulmonary function among young adults (mean age 19 years) who had moderate to severe BPD as preterm neonates found that over 80% showed signs of premature emphysematous changes (25). Hyperoxia may be a cause of alveolar simplification, in part by reducing cell proliferation and airway branching. O'Reilly has shown in laboratory animals that hyperoxia induces p-21, an inhibitor of cell proliferation that has the potential to inhibit alvelolar and airway growth (26;27). Whether management of babies with lower rather than higher saturation targets reduces oxygen exposure to the lung and thereby promotes normal lung growth prevents alveolar simplification has not been studied. The SUPPORT – Breathing Outcomes school age PFT study would measure vital capacity provide inference about lung growth and alveolarization.

Excess Respiratory Symptoms Persist Beyond Pulmonary Function Abnormalities in Preterm Infants
Preterm infants, especially those who develop BPD, are at greatest risk for persistent respiratory symptoms, need for pulmonary care and abnormal pulmonary function during childhood (12;14;23;28). In cohort studies, the prevalence of respiratory symptoms and need for pulmonary care often exceeds the prevalence of objective measurements of abnormal pulmonary function (11;14;29). In a recent study of former preterm compared with healthy term infants assessed as young adults (21 years of age), subjects born preterm had significantly more respiratory symptoms yet no difference in pulmonary function measurements of airway obstruction or reactivity (30). The SUPPORT-School Age Breathing Outcomes Study will measure both prevalence of respiratory symptoms and need for care and objective measures of pulmonary function. We hypothesize that BPD and respiratory symptoms at 18-22 months of age will be more closely predictive of ongoing respiratory symptoms and need at 6-7 years of age than of abnormal pulmonary function.

NIH Recognizes Need for Further Study of Developmental Origins of Altered Lung Physiology
In May 2008, NHLBI issued a request for applications (RFA Number: RFA-HL-08-009), entitled "Developmental Origins of Altered Lung Physiology and Immune Function". The RFA, funded through a R01 mechanism, calls for applications "that propose to perform research that will enhance the understanding of how the pre- and postnatal environments affect the interplay of the lung and immune system during development resulting in sustained changes in lung physiology and immune function that compromise respiratory health and outcomes." Although not responsive to the RO1 due to the lack of associated animal studies, the SUPPORT–School Age Breathing Outcomes Study provides a unique opportunity to study the effect of management with randomized ventilation and oxygen saturation targets on later "second hit" environmental and infectious lung injury and repair.

Summary
The SUPPORT – School Age Breathing Outcomes Study represents a unique opportunity to study the causes of short and long term pulmonary morbidity of preterm infants for several reasons, including:

- Longitudinal follow-up studies of randomized, experimental oxygen and mechanical ventilation exposure are not available and, if not performed by the NICHD Neonatal Research Network, unlikely to be performed in the future.
- By following infants exposed to randomized, experimental exposure to concentrated oxygen and mechanical ventilation through childhood, a "natural experiment" is created in which the effects of early neonatal respiratory exposures on the sensitivity or reaction to subsequent environmental exposures can be studied. Insights gained from this study may provide new insights into the mechanisms causing pulmonary morbidity among preterm infants and to create future opportunities to prevent or treat chronic respiratory disease in these infants.
- Because of its longitudinal design, valuable information will be gained on the natural history of pulmonary morbidity in preterm infants during childhood and allow the burden of treating preterm infants with respiratory to be quantified.

Methods: The methods described below describe the study population, field work necessary to track potentially eligible patients to school age and gain consent for participation. The methods also describe the tools used to measure the primary and main secondary pulmonary outcomes and collect environmental respiratory exposures that might modify those outcomes.

Study Population:

Inclusion

- Infants enrolled in SUPPORT and Breathing Outcomes Secondary Study
- Capable of performing spirometry
- Consent to participate in School Age Breathing Outcomes

Exclusion

- Failure to participate in School Age Breathing Outcomes

Field Work:

Tracking patients: Tracking will be essential to ensure the best possible follow-up. The tracking program and tracking tool will be similar to those used in the Neuroimagaing Secondary Study (Appendix 1).

Between 18-22 months and 6-7 years of age, two contacts per year will be attempted, one phone call and one yearly mailing with a birthday card and information about respiratory health of preterm infants. Regular contact will aid in keeping contact information of study patients up to date. Two contacts (1 phone and 1 mail contact) per year over 5 years, 10 total, at $35/contact is a total budgeted cost of $350/patient. Although difficult to estimate, it is very likely that the tracking costs of School Age Breathing Outcomes will be substantially reduced by overlap with tracking procedures and effort performed as part of the neuroimaging secondary study.

Consent:

Consent to contact families for possible 6-7 year follow-up will be sought at the 18-22 month visit. Tracking will then commence as noted above. For patients beyond 18-22 months of age when the School Age Breathing Outcomes Protocol is implemented, formal signed consent will be obtained at the time of the 6-7 year follow-up visit. It is expected that the consent process will take ~1/2 hour.

Patient incentive to participate: To facilitate recruitment and retention, a $100 honorarium will be offered to each patient choosing to participate in the SUPPORT – School Age Breathing Outcomes Study.

Outcomes:

Primary Outcome:

- Ratio of forced expiratory volume in 1s (FEV_1) divided by that predicted based on the patients weight, height and sex

Secondary Outcomes:

- Forced vital capacity (FVC)
- Forced midexpiratory flow rate (FEV_{25-75})
- Ratio of FEV_1 to FVC (FEV%)
- Peak expiratory flow velocity (PEF)
- Resting respiratory rate and oxygen saturation
- Prevalence of symptomatic airway dysfunction measured using a symptom questionnaire
- Use of respiratory medications in the preceding 12 months
- Need for medically attended outpatient pulmonary care (ED or office) in the preceding 12 months
- Need for respiratory related hospitalization in the preceding 12 months
- Assessment of correlation between FEV_1 and respiratory symptoms at 6-7 years of age
- Among infants with family history of asthma, to compare symptomatic airway dysfunction, need for outpatient pulmonary care and pulmonary function at 6-7 years of age by SUPPORT intervention.
- Association between respiratory symptoms and measured PFT abnormalities at 6-7 years of age.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Pulmonary Function Testing:
In 2007, The American Thoracic Society and European Respiratory Society issued a statement confirming that technically acceptable spirometry is possible in preschool aged children and provided guidelines on the performance and reliability of pulmonary function testing in this age group. *Pulmonary function testing for the SUPPORT – School Age Breathing Outcomes Study will be performed in accordance with the ATS / ERS statement (31).*

Spirometry is commonly performed in adults and in school age children (those aged 6–16 yr), but recent reports have confirmed that preschool children are also able to perform these maneuvers (32-38). To optimize the accuracy, reproducibility and comparability of spirometry data across centers, the SUPPORT – School Age Breathing Outcomes Study will adhere to the following ATS / ERS recommendations (31):

1. The flow–volume curve ideally should be presented to the operator in real time with the ability to also view the volume–time trace.
2. The following indices from each spirometry attempt should be available to the operator before the next attempt: FVC, FEV in *t* seconds (FEV*t*), back-extrapolated volume (VBE), and the point at which flow ceases, presented as a proportion of peak expiratory flow (PEF).
3. If it is the subject's first attempt at spirometry, a period of training is essential. The child should be familiarized with the equipment and technician.
4. Interactive computerized incentives (software used to motivate the patient) will be used to encourage the maneuver. The incentive to be used will be a volume-driven incentive or a flow- and volume-driven incentive during the time the maneuvers are to be recorded.
5. Posture and noseclip use will be recorded and reported.
6. The operator should observe the child closely to ensure there is no leak, and that the maneuver is performed optimally.
7. A minimum of three maneuvers will be recorded, but no maximum number is stipulated.
8. Both volume–time and flow–volume curves should be visually inspected. The attempt should be excluded if the flow–volume curve does not demonstrate a rapid rise to peak flow, and a smooth descending limb, without evidence of cough or glottic closure.
9. If the VBE is greater than 80 ml, or 12.5% of FVC, then the curve should be reinspected, but need not necessarily be excluded.
10. If cessation of flow occurs at greater than 10% of peak flow, then this maneuver should be classified as showing premature termination. It may be possible to report timed expiratory volumes from such a maneuver, but FVC and forced expiratory flows should not be reported.
11. The highest FEV*t* and FVC should be reported, after examining data from all of the usable curves, even if they do not come from the same curve.
12. The starting point for FEV*t* should be determined by back extrapolation.
13. The method of identifying best flows should be recorded and reported. If flows are to be reported from the "best" maneuver, then this should be identified as that with the highest sum of FEV0.5 and FVC.
14. Ideally, the subject should produce at least two acceptable curves, where the second highest FVC and FEV*t* are within 0.1 L or 10% of the highest value, whichever is greater. If a single satisfactory maneuver is recorded, then these results should not be excluded simply because of poor repeatability. The number of technically satisfactory maneuvers and the repeatability results should always be reported.

Respiratory Symptom and Healthcare Utilization Questionnaire: Literature suggests that pulmonary morbidity as measured by both respiratory symptoms and pulmonary function testing persists through school age. A recent study suggests that a tendency toward greater frequency and severity of respiratory symptoms may persist beyond the age at which objective pulmonary function tests have normalized.

The respiratory symptom and healthcare utilization questionnaire to be used in this study will be a modified version of the International Study of Asthma and Allergies in Childhood (ISAAC) Questionnaire (separate file). This questionnaire has been well validated in multiple asthma related studies and used in the school age

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

follow-up studies of respiratory outcome of preterm infants. (12;39-42). The ISAAC questionnaire is very strong in screening for and quantifying the severity of respiratory symptoms and collecting information on respiratory exposures, triggers and the effects of respiratory symptoms on quality of life. Modifications to the ISAAC Questionnaire that will be introduced by the School Age Breathing Outcomes Investigators are addition of several questions asked previously as part of the Breathing Outcomes Study to obtain health care utilization and respiratory medication histories. From these questions, data on the following respiratory exposures will be obtained:

Primary Exposures:
Environmental Tobacco Smoke (ETS): Presence or absence of ETS exposure will be ascertained using questions shown by Dr. Wakefield and colleagues to correlate with cotinine levels (43;44). These questions were administered as part of the Breathing Outcomes Study at 18-22 months of age and will be administered again at 6-7 years of age.

Environmental Allergens: The number of inhaled environmental allergens to which a child was exposed will be ascertained using the ISAAC-based School Age Breathing Outcomes Questionnaire.

Acute Respiratory Infections: Number of acute respiratory infections receiving medical attention by 18-22 months of age will be ascertained using the Breathing Outcomes 18-22 month Questionnaire, questions # 6a, 7a or 8a of the Breathing. Additional history of the number of number of respiratory infections in the preceding 12 months will be obtained at 6-7 years of age.

Sample Size:
The Newborn Lung Project, a cohort study of VLBW infants at school age served as the basis for the assumptions used to calculate sample size. The Newborn Lung Project, a cohort study of 265 VLBW infants, studied FEV1 ratio (ratio of observed FEV1 divided by that predicted based on the patients weight, height and sex) at school age in patients with and without BPD (n - 59, FEV1 ratio - 0.78, sd - 0.13 and n - 206, FEV1 ratio - 0.88 and sd - 0.14, respectively) (14). Based on these assumptions, an effect size table was calculated (Appendix 2). In the base case (highlighted box in Appendix 2), 120 patients (60 in each SUPPORT treatment group) will be sufficient to detect an 8% difference in FEV1 with 90% power and two-sided alpha of 0.05. An 8% absolute difference in FEV1 ratio was assumed in the base case because it is both clinically significant and a conservative estimate of the expected differences between groups.

Number of Available Patients
Primary Outcome:
Based on enrollment to date, at least 750 patients will be enrolled into the SUPPORT – Breathing Outcomes Study at completion of the study. Assuming a 10% loss to follow up at 18-22 months (estimates based on current enrollment and follow up data), 25% loss to follow up at 6-7 years of age and 25% of potentially eligible patients being unable to perform testing, 384 patients are expected to be available to study (Appendix 3). Based on the 2x2 randomized design of SUPPORT, an estimated 96 patients per study intervention group (Figure 1, cells I-IV) and 192 patients per primary intervention comparison (e.g. - Figure 1, cells I & III vs. cells II & IV) will be available for study.

Fig. 1 NICHD SUPPORT Trial Design, 2 x 2 factorial

Randomized Intervention	Low SpO2 85% to 89%	High SpO2 91 to 95%
Treatment Early CPAP	I Early CPAP + Low SpO2 (96 patients)	II Early CPAP + High SpO2 (96 patients)
Control Prophylactic/Early Surfactant	III Control + Low SpO2 (96 patients)	IV Control + High SpO2 (96 patients)

Hence, the available sample of 192 patients per primary intervention comparison (e.g. - Figure 1, cells I & III vs. cells II & IV) will be more than adequate to detect an 8% differences in FEV1 ratio through a wide range of assumptions of treatment effect (detectable difference) and standard deviation of the data (Appendix 2).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Analysis by each of 4 treatment groups: With an estimated 96 available patients per each of the 4 treatment groups defined in Figure 1, a sample size of 120 patients will be adequate to detect an 8% difference in FEV1 between each primary treatment group and allow analysis of potential synergy between combinations of treatment modalities.

Secondary Outcomes:

Subgroups of patients with or without BPD: The available study population will be adequate to allow analysis of treatment effect in important subpopulations, including comparison of the SUPPORT intervention effect among infants with and without BPD. Assuming a 35% rate of BPD among study patients, 136 infants (34 per treatment cell, Figure 2, cells I-IV) would be expected to have BPD and 248 infants would not. Again a total of 120 patients would be necessary to detect an 8% difference in FEV1 between SUPPORT Study interventions assuming 90% power, alpha of 0.05, and standard deviation of 12%. Based on these assumptions, the available sample of 136 patients per primary intervention comparison (e.g. - Figure 2, cells I & III vs. cells II & IV) will be more than adequate to clinically significant differences through a wide range of assumptions of treatment effect (detectable difference) and standard variation of the data (Appendix 2).

Fig. 2 - Available Subgroup of Patients with BPD

Randomized Intervention	Low SpO2 85% to 89%	High SpO2 91 to 95%
Treatment Early CPAP	I Early CPAP + Low SpO2 (34 patients)	II Early CPAP + High SpO2 (34 patients)
Control Prophylactic/Early Surfactant	III Control + Low SpO2 (34 patients)	IV Control + High SpO2 (34 patients)

Analysis by Environmental Tobacco Smoke (ETS) Exposure: Based on assumptions above and assuming 30% of study patients will have environmental tobacco smoke (ETS) exposure, a total of 116 patients (58 per cell I & II in Figure 3) will have ETS exposure. Based on data from former VLBW infants with ETS exposure (4), a larger detectable difference between primary study intervention (high vs. low targeted saturation) is expected. The available study population will be adequate to detect 8% difference in FEV1 between high and low targeted oxygen saturation group among patients with or without ETS exposure with 80% power or a 10% difference between groups with 90% power (Appendix 2 – Sample Size Table). Evaluating the effects of ETS exposure will provide important information on whether the pulmonary benefits of SUPPORT confer resistance to secondary pulmonary irritants such as ETS exposure. Similar analyses will be performed for subgroups of infants with history of acute respiratory infections and inhaled allergen exposure during childhood.

Fig. 3 Available Subgroup of Patients exposed to ETS

	Low SpO2 85% to 89% 192 patients	High SpO2 91 to 95% 192 patients
Environmental Tobacco Smoke Exposure	I 58 Patients	II 58 Patients
No Environmental Tobacco Smoke Exposure	III 144 patients	IV 144 Patients

Analysis Plan

Analysis of primary dichotomous outcomes will be performed by chi square test and presented as a relative risk for development of that outcome. Number of outpatient pulmonary visits for respiratory illnesses will be presented as median values. The Wilcoxon Rank Sum test, a non-parametric alternative to the two-sample ttest, will be used to test for differences between the two groups. Statistical analyses will need to consider the effect of multiple comparison groups on the level of statistical significance. All analyses will be performed in conjunction with the Research Triangle Institute (RTI, North Carolina). Data will be presented as shown in Appendix 4. Pulmonary function tests will be reported as z-scores, in accordance with the ATS / ERS recommendations for reporting PFT results in preschool and school age children.

Budget:

In Appendix 3, a total budget of $396,400 is estimated. The budget allows for start up costs of $1,000 per center for IRB and consent preparation, $2500 for equipment and capitated costs for patient tracking and follow up ($350 per patient), spirometry ($350 per patient), administration of the Respiratory Symptom and Healthcare Utilization Questionnaire ($50 per patient) and a participant honorarium ($100 per patient).

Appendix 1. – Tracking Questionnaire

NICU Network	**SUPPORT School Age Breathing Outcome Secondary 6-7 Year Tracking Form (SEF 01)**

Center: __ Site No: __ Network No: __ __ __ __ Birth Order: __ Mother's Initials: __ __ __, __ __ Follow-up No.: __ __ __ __

This form should be completed for all children enrolled in the SUPPORT Breathing Outcomes secondary study who were alive at the 18-22 month follow up visit.

A. STATUS INFORMATION

1. Were you able to contact the family? Y N

1a . IF YES: (enter all codes that apply from below) ___ ___ ___ ___ ___

1=Saw the family in person
2=Spoke on the phone
3=Emailed and received a reply
4=Sent letter/postcard and have received a reply via mail
5=Other_____

1a1. Date of contact __ __/__ __/__ __ __ __
Month Day Year

1b . IF NO: (enter all codes that apply from below) ___ ___ ___ ___ ___

1=Left voicemail(s) at number that was definitely still the family's and have not heard back
2=Left generic voicemail(s) at number that might not be the family's and have not heard back
3=Sent mail to last known address and have not received response
4=Sent mail to last known address and it was returned
5=Other_____

2. 3-4 year outcome: (enter one code from below) ___

1=Family is planning on attending the 6-7 year visit
2=Family declines further contact
3=The child is deceased
4=All contact currently lost, continuing to look
5=Other_____

B. FORM COMPLETION

1. Date form completed: __ __/__ __/__ __ __ __
Month Day Year

2. Initials of person completing this form: ___ ___ __

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Appendix 2 – Estimates of Available Study Population and Necessary Sample Size

Available Patients

Estimated Available Study Population	**n**	**Remaining N**
Total Enrolled Breathing Outcomes Patients (# anticip	750	750
Loss to follow up at 18-22 months of age (10%)	75	675
Loss to follow up at 6-7 years of age (25%)	166	509
Unable to perform (25%)	125	384
Total Available Study Subjects		**384**

Available Subjects for Subroup Analysis	**Patients (N=384) With BPD (n)**	**Without BPD (n)**
35% Incidence of BPD	136	248
45% Incidence of BPD	173	211

Sample Size Table

	Detectable Difference (Absolute Value)	**High Sat Group**	**Low Sat Group**	**Sample Size (total for 2 groups) 90% Power**	**80% Power**
Primary Outcome					
Calculation using range of mean difference assumptions					
FEV1, mean (sd)	0.06	0.82 (0.14)	0.88 (0.13)	214	160
FEV1, mean (sd)	0.08	0.80 (0.14)	0.88 (0.13)	120	90
FEV1, mean (sd)	0.10	0.78 (0.14)	0.88 (0.13)	78	58
Calculation using range of standard deviation assumptions					
FEV1, mean (sd)	0.10	0.78 (0.14)	0.88 (0.14)	84	62
FEV1, mean (sd)	0.10	0.78 (0.16)	0.88 (0.16)	108	82
Calculation using range of standard deviation assumptions					
FEV1, mean (sd)	0.08	0.80 (0.14)	0.88 (0.14)	130	98
FEV1, mean (sd)	0.08	0.80 (0.16)	0.88 (0.16)	170	126
Calculation using range of standard deviation assumptions					
FEV1, mean (sd)	0.06	0.82 (0.14)	0.88 (0.14)	230	172
FEV1, mean (sd)	0.06	0.82 (0.14)	0.88 (0.14)	300	224

Appendix 3 - Budget

SUPPORT - School Age Breathing Outcomes Study

Proposed Budget

Start up costs	**Unit Cost**	**Total (20 Centers)**
IRB	$1,000	$20,000
Spirometry Equipment (Cardinal Health Microloop)	$2,500	$50,000
Sub-total Start up Costs		**$70,000**
Capitated Costs	**Per Capita**	**Total (n=384)**
Tracking and Follow up Between 18-22 months and 6-7 years 2 contacts / yr for 5 years (1 mail and one phone contact) @ $35/contact - 10 total	$350	$134,400
Spirometry Testing (pre - post bronchodilator)	$350	$134,400
Questionnaire	$50	$19,200
Participant Honorarium	$100	$38,400
Sub-total Capitation Costs		**$326,400**
Data Center Costs		**TBD**
Grand Total		**$396,400**

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

School Age Breathing Outcomes

Modified ISAAC Questionnaire for 6/7 year olds

Enter name and relationship code of the person being interviewed*:

1a. Name: _____ _____ 1b. Relationship Code: |___|___|___|

001 - Mother of Child
002 - Father of Child
301 - Adoptive mother
302 - Adoptive father

Other: _____
Common codes are listed here for other relationships, please look up relationship code from Appendix D of the Breathing Outcomes Manual of Operations and enter above.

2. Type of Interview: 1~ Face to Face 2~ Telephone

Instructions:
Parents or guardians expressing concerns regarding their child's breathing should be advised to discuss them with the family's primary care physician.

Interview begins:

Some of these questions will be familiar to you.

In the past 12 months.....

3. How many times has your child visited a doctor's office?
None ☐
1-3 ☐
4-12 ☐
More than 12 ☐

3a. How many of these times were because of wheezing or breathing problems?
None ☐
1-3 ☐
4-12 ☐
More than 12 ☐

In the past 12 months .....

4. How many times has your child visited an Emergency Department (Emergency room)?
None ☐
1-3 ☐
4-12 ☐
More than 12 ☐

4a. How many of these times were because of wheezing or breathing problems?
None ☐
1-3 ☐
4-12 ☐
More than 12 ☐

In the past 12 months .....

5. How many times has your child stayed in the hospital one or more nights in a row?
None ☐
1-3 ☐
4-12 ☐
More than 12 ☐

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

5a. How many of these times were because of wheezing or breathing problems?

- None ☐
- 1-3 ☐
- 4-12 ☐
- More than 12 ☐

Core questionnaire for wheezing

6. Has your child ever had wheezing or whistling in the chest at any time in the past?

- Yes ☐
- No ☐

IF YOU HAVE ANSWERED "NO" PLEASE SKIP TO QUESTION 11

7. Has your child had wheezing or whistling in the chest in the past 12 months?

- Yes ☐
- No ☐

IF YOU HAVE ANSWERED "NO" PLEASE SKIP TO QUESTION 11

8. How many attacks of wheezing has your child had in the past 12 months?

- None ☐
- 1 to 3 ☐
- 4 to 12 ☐
- More than 12 ☐

9. In the past 12 months, how often, on average, has your child's sleep been disturbed due to wheezing?

- Never woken with wheezing ☐
- Less than one night per week ☐
- One or more nights per week ☐

10. In the past 12 months, has wheezing ever been severe enough to limit your child's speech to only one or two words at a time between breaths?

- Yes ☐
- No ☐

11. Has your child ever had asthma?

- Yes ☐
- No ☐

12. In the past 12 months, has your child's chest sounded wheezy during or after exercise?

- Yes ☐
- No ☐

13. In the past 12 months, has your child had a dry cough at night, apart from a cough associated with a cold or chest infection?

- Yes ☐
- No ☐

14, Since our last contact with you, has your child had bronchiolitis, bronchitis, or pneumonia diagnosed by a doctor?

- Yes ☐
- No ☐

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

15. How much does your child weigh?: ☐ kg / stone / pounds
(please circle the measurement you used)

16. How tall is your child?: ☐ metres / centimetres / feet and inches
(please circle the measurement you used)

17. In the past 12 months, how often, on average, did your child eat or drink the following?: (Please leave blank if you do not know what a food is)

	Never or occasionally	Once or twice per week	Three or more times a week
Meat (e.g. beef, lamb, chicken, pork)	☐	☐	☐
Seafood (including fish)	☐	☐	☐
Fruit	☐	☐	☐
Vegetables (green and root)	☐	☐	☐
Pulses (peas, beans, lentils)	☐	☐	☐
Cereal (including bread)	☐	☐	☐
Pasta	☐	☐	☐
Rice	☐	☐	☐
Butter	☐	☐	☐
Margarine	☐	☐	☐
Nuts	☐	☐	☐
Potatoes	☐	☐	☐
Milk	☐	☐	☐
Eggs	☐	☐	☐
Fast food/burgers	☐	☐	☐

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

18. How many times a week does your child engage in vigorous physical activity long enough to make him/her breathe hard?:

- Never or occasionally ☐
- Once or twice per week ☐
- Three or more times a week ☐

19. During a normal week, how many hours a **day (24hours)** does your child watch television?:

- Less than 1 hour ☐
- 1 hour but less than 3 hours ☐
- 3 hours but less than 5 hours ☐
- 5 hours or more ☐

20. In your house, what fuel is usually used for cooking?:

- Electricity ☐
- Gas ☐
- Open fires ☐
- Other – Please specify ☐

21. In your house, what fuel is usually used for heating?:

- Electricity ☐
- Gas, kerosene, paraffin ☐
- Wood, coal, oil ☐
- Other – Please specify ☐

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

22. In the first 12 months of life, did your child have any antibiotics?:

Yes ☐

No ☐

23. How many older brothers and sisters does your child have?: ☐ brothers and sisters

24. How many younger brothers and sisters does your child have?: ☐ brothers and sisters

25. Was your child born in (NZ - See instructions)?:

Yes ☐

No ☐

26. How many years has your child lived in (NZ - see instructions)?: ☐ years

27. What level of education has the child's mother received?: (local wording)

Primary school ☐

Secondary school ☐

College, university or other form of tertiary education ☐

28. How often do trucks pass through the street where you live, on weekdays?:

Never ☐

Seldom ☐

Frequently through the day ☐

Almost the whole day ☐

29. Did you have a cat in your home during the first year of your child's life?:

Yes ☐

No ☐

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

30. In the past 12 months, have you had a cat in your home?:

Yes ☐

No ☐

31. Did you have a dog in your home during the first year of your child's life?

Yes ☐

No ☐

32. In the past 12 months, have you had a dog in your home?: Yes ☐

No ☐

33. In your child's first year of life did he/she have regular (at least once a week) contact with farm animals (e.g. cattle, pigs, goats, sheep or poultry)*?:

Yes ☐

No ☐

34. Has this child's Mother had regular (at least once a week) contact with farm animals (e.g. cattle, pigs, goats, sheep or poultry) while being pregnant with this child?

Yes ☐

No ☐

35. Does your child's mother (or female guardian) smoke cigarettes?:

Yes ☐

No ☐

If **YES**, about how many cigarettes does the child's mother (or female guardian) smoke each day? ☐ number of cigarettes

36. Does your child's father (or male guardian) smoke cigarettes?:

Yes ☐

No ☐

If **YES**, about how many cigarettes does the child's father (or male guardian) smoke each day? ☐ number of cigarettes

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

37. Did your child's mother (or female guardian) smoke cigarettes during your child's first year of life?:

Yes ☐

No ☐

38. How many people living in the house smoke cigarettes, people including parents?: ☐

OXYGEN

39. Since our last contact with you, has your child received oxygen therapy at home?
1~ Yes 2~ No *Skip to Question 41*

If yes to Questions 40

40a. Is your child currently on any oxygen therapy at home?
1~ Yes 2~ No *Skip to Question 41*

If yes, indicate Yes or No for each: *lpm = liters per minute

40b. Oxygen cannula	1~ Yes	2~ No	FiO2_____	lpm*_____
40c. Oxygen hood	1~ Yes	2~ No	FiO2_____	lpm*_____
40d. Ventilator	1~ Yes	2~ No	FiO2_____	lpm*_____

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

MEDICATIONS *(Enter responses in table. Do not prompt for each medication in the Medication Code List below.)*

The next questions involve the medicines your child is taking for breathing problems.

40. Since our last contact with your, what medicines has your baby taken, including medicines taken by a nebulizer or breathing machine at home?	40a. Code	40b. Does he/she take that medicine everyday, sometimes or only when sick? *(repeat for each medication)*
1		1❑ Everyday 2❑ Sometimes 3❑ Only when Sick
2		1❑ Everyday 2❑ Sometimes 3❑ Only when Sick
3		1❑ Everyday 2❑ Sometimes 3❑ Only when Sick
4		1❑ Everyday 2❑ Sometimes 3❑ Only when Sick
5		1❑ Everyday 2❑ Sometimes 3❑ Only when Sick
6		1❑ Everyday 2❑ Sometimes 3❑ Only when Sick
7		1❑ Everyday 2❑ Sometimes 3❑ Only when Sick

Medication Code List:

***Rescue medicines*:**
1 Albuterol
2 Proventil
3 Serevent
4 Ventolin
5 Volmax
6 Xopenex

Other Inhaled medications:
7 Cromolyn (Intal)
8 Nedocromil (Tilade)

Inhaled steroids:
9 Advair
10 Aerobid
11 Azmacort
12 Beclovent
13 Flovent
14 Vanceril
15 Pulmicort

Systemic steroids:
16 Decadron
17 Prednisone
18 Prednisolone

Leukotriene blocker:
19 Accolate
20 Singulair

Methylxanthines:
21 Theophylline

Diuretic medications:
22 Diuril
23 Lasix
24 Aldactizide
25 Aldactone

Miscellaneous / Non-specific
26 Nebulizer
27
Other_____

Thank you very much for your help with this questionnaire. We appreciate your assistance.

Subject: RE: NICHD NRN SUPPORT TRIAL ROP Adjudication Process conference call

Dear all,

We have scheduled a conference call for **Friday, October 23, 2009 from 4:00 = 5:00PM (EST)** to discuss a process to adjudicate cases with unclear ROP outcome. Contacts below:

Call in number: 1-866-675-(b) (6)
Pass code: (b) (6) (the "#" sign at the end is required)

Thanks,
Kris

Subject: NICHD NRN SUPPORT TRIAL ROP data adjudication conference call

Dear all,

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

We will have the NICHD NRN SUPPORT Trial data lock on 10/20/09 and would like to ask that you be part of an adjudication committee to determine acute final ROP status (if possible) for cases that are not straight forward. We would like to have this conference call on **Friday, October 23, 2009 from 3:00 = 5:00PM (EST).** We would be sending the data for case reviews on 10/22/09. Currently, there are about 50 cases where the infant had one exam in zone 3 (instead of the two consecutive exams required to meet our final status requirement) and about 50 who only had exams in zone 2. The study subcommittee may determine these later cases are classified as undetermined per the study manual definition but after data lock we will have a better idea of cases needing review. I have attached the study manual for reference.

Please let me know if you are willing and available this date and time.
Thanks,
Kris

Instructions for SUPPORT Form SUPP10: ROP Outcomes and Tracking (From the SUPPORT Manual of Operations)

The purpose of this form is to track and document the acute ROP outcome of each eye. Tracking the course of ROP should begin with the first examination and will generally be much easier if the coordinator attends the examinations and asks the ophthalmologist in person about the categories to be recorded.

Data may be entered in the database from the form after each examination, or may be entered when the infant reaches "acute/final" status. However, monitoring of the examinations and progress will be much more complete and helpful if these are entered after each examination.

Complete this form for all enrollees in SUPPORT who survive to have their first eye examination. This normally is scheduled at 31 weeks postmenstrual age (but not earlier than 4 weeks after birth).

Record the data for each eye examination until each eye has reached "acute/final" status (see definition below in 15.2). This will sometimes include examinations following discharge home or transfer to another hospital.

1. **Date of Exam**
   If a confirming examination is conducted, each should be separately recorded.

2. **Location of Exam**
   Code 1= inpatient for the primary hospital where the infant has been cared for, including other Units in that same hospital (step down units, pediatric intensive care, surgical care units, etc.)

   Code 2=Outpatient for examinations in the outpatient ophthalmology department, private ophthalmologist's office or other outpatient visits. Include infants at a chronic care facility transported to the physician's office for an examination.

   Code 3= Transfer Hospital when infants have been back transferred to a referring hospital or regional hospital.

   Note: Outpatient and back transfer hospitals can be a common source of infants missing examinations and "slipping through the cracks". Be particularly attentive to ensuring timely repeat examinations in these cases and ensure that the family is aware of the importance and critical timing of the examinations.

3. **Lowest zone:** Record the lowest zone that contains vessels that end before crossing out of that zone. This may be zone I (the most immature), zone II (intermediate) or zone III (most mature). The ophthalmologist normally records this on the eye examination form. The most common for SUPPORT infants will be zone II at the early examinations. There may be vessels recorded in:
   - zone I and II (you record zone I)
   - zone I only (you record zone I)
   - zone II only (you record zone II)
   - zone III only (you record zone III)

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Note that by convention, disease is never to be recorded in zones II and III in the same eye. If the two nasal clock-hours are not fully vascularized, by convention, no vessels in that eye are to be recorded in zone III. If they are fully vascularized, the all the rest of that eye's vessels are in zone III.

4. **Highest stage in lowest zone** (not to be used if eye has had surgery)
Look first at the lowest zone that has vessels ending in it (see previous answer). Then look to see if there is ROP in any of the clock hours of that zone. Choose the highest stage of ROP in that zone to record.

Examples:

If the eye has vessels ending in just zone I, but no ROP, the highest stage is zero.

If the eye has vessels ending in zone I and zone II and the ROP in zone I is stage 2 while the ROP in zone II is stage 3, the highest stage in the lowest zone (I) is stage 2.

If the eye has vessels ending in zone I, but there is no ROP in zone I, but there is stage 2 and stage 3 ROP in zone II, the answer would be 0=no ROP in the lowest zone.

5. **Highest stage in any zone** (not to be used if eye has had surgery)
Look at the stage of ROP around the 12 clock-hours of the recorded examination. Choose the highest stage to record. In rank order going from lowest to highest the order is 0, 1, 2, 3, 4a, 4b, 5. The other categories are for less common cases.
- Code 4 = stage 4a or 4b is a partial retinal detachment
- Code 5 = stage 5 which is a total retinal detachment
- Code 6 = Post laser/cyro (do not use stages)
- Code 9 = Old scars, but no active ROP

6. **"Plus disease"**
This is recorded by the ophthalmologist as present or not. Sometimes they provide comments like 'borderline plus' or 'possible early plus disease' or 'mild dilation, but not plus disease'. In these cases, do not record 'plus disease' as present. If the ophthalmologist records plus disease by quadrants, two or more quadrants are required to meet criteria for plus disease (i.e. only one quadrant of dilated/tortuous vessels is not sufficient.).

7. **Threshold (New Type 1 threshold per ETROP)**
The ophthalmologist who diagnoses threshold ROP needing surgery will normally state this prominently on the examination form. The criteria for the new threshold are any of the following four findings:

If in zone I: stage 3 ROP, even without plus disease
plus disease with any stage ROP

If in zone II: plus disease with stage 2 ROP
plus disease with stage 3 ROP

There may be times when disease is worse than this, but it should still be recorded as threshold. There will be some times when the judgment of the retinal surgeon and

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

neonatologist will be not to administer treatment (laser or cryo), even when there is new threshold. Normally infants are then followed extremely closely (every few days repeat examinations).

8. **Surgery**
   For each examination date, record if surgery is performed on that day. (mostly will be no). If surgery was previously performed, but not on the day of that examination, record 0

9. **Post-surgical Retinal Detachment after surgery**
   This at first looks like a repeat of the question asking for stage of ROP, but it is not since it is intended to be used only after surgery has occurred.

10. Final Acute Status Lost to Follow-up at 55 weeks PMA
    Complete this question **only** for the final eye exam entered.

    Record 'N' if the last examination meets criteria for final acute status reached (see section 15.2 below).

    Record 'Y' if the final 'acute' ROP status is permanently missing because the infant is lost-to-follow up. For example, the last exam is not yet mature, or not yet in zone III for the second time in a row, or the baby still has ROP, but had not reached criteria for surgery. All attempts must have been made to capture this data from the follow up exams, and it is coded 'Y' as missing only when there was no final exam done (parents did not bring infant in).

    By the time an infant has reached 55 weeks PMA, the eye disease will have reached final status, whether we know about it from an examination or not. That is why we make this determination at this time. If it is later learned that examinations actually were done, the results can be entered on the form with a late correction/edit.

    Therefore, if you know the infant is less than 55 weeks PMA and has not had an exam that meets the final/acute criteria, you are still trying to get the family to bring the baby in for exams because it is clinically important and also will give you a primary study outcome. If it is now past 55 weeks, you may give up trying to get them to come in because it's too late to identify disease that could be treated, and the time for the clinical outcome for the study is also past. Late outcomes will be collected at the 18-22 month follow up examination.

    Potential merit of later exams: Most likely, they will reassure the infant that the eyes have healed. They may detect an important need for glasses at 6-9 months after birth. If the outcome is retinal detachments, the parents will learn the baby is not going to see and needs to be referred for early intervention. In either event, late exams that show retinal detachments will confirm that once upon a time, the baby did have bad ROP. Late exams that show good outcomes will NOT tell us if they once had ROP that has now regressed (healed).

    Note: even in these circumstances where we have given up, the infant will still be tracked down for the 18-22 month follow up visit. At that time they are asked if any eye surgery was done after discharge / status. If yes, what surgery. If it was for ROP,

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

then that will become a final status revision. Also, even if no surgery was done, but the child has experienced vision loss *from ROP*, this would also be a final outcome.

Note that some infants have vision loss that is not from ROP. This is usually "cortical vision loss" and is from brain injury.

11. Final ROP Status determined at 18 Moth Follow Up
Complete this question **only** for the final eye exam entered.

Answer this question as 'N' if the final acute status was already determined before 55 weeks PMA. That is, "no, we did not determine the final outcome based on the 18-22 month exam."

Also, answer this question as 'N' if the final status was not determined by 55 weeks PMA, AND it was not determined at the 18-22 month visit either. This would happen if there were no 18-22 month examination. It would also happen if there were an 18-22 month examination, but the parents report no eye surgery and no other eye exams so we don't know what happened to the ROP.

You can record 'Y' for the final ROP status obtained during the 18-22 month follow up visit only if the parents are now reporting to you eye surgery for ROP that you had not learned about before, or they are telling you about eye exams that you have not learned about before (or else you would have recorded it before). If this is the case, reports from the exam(s) and/or surgery should be obtained to determine what has happened. These data will likely require ophthalmology input to determine if the primary ROP outcome was reached. Examples: A. ROP can be assumed (imputed) to have reached surgical criteria if the infant's subsequent surgery is vitrectomy for retinal detachment, or is an exam under anesthesia with a diagnosis of ROP stage 4A, 4B or stage 5 ROP, or retinal fold crossing the macula. B. ROP may not have met laser/CRYO criteria if the surgery was for strabismus (crossed eye), plugged tear duct, or only examination under anesthesia, for example to rule out glaucoma.

Acute/final Status

An eye is 'acute/final" when it reaches one of the following points in time:
These can be a good outcome (favorable) as the ROP heals (regresses), or it can be the primary outcome variable event (unfavorable).

Favorable

- Vessel growth if mature to the ora serrata in all clock hours
- Vessels in zone III for two sequential eye examinations

Unfavorable

- type I threshold ROP
- Laser (or cryo or both) surgery for acute ROP
- retinal detachment stage 5 retinal detachment stage 4b

Other

- Infant dies.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Instructions for 18 Month Follow-Up Exam Questions Related to Vision (From the Follow-Up Manual of Operations)

Record separately for each eye, a-e; Record '1' Yes, if in the examiner's judgment the child has strabismus, nystagmus, or roving eye movements. Record '2' No, if the examiner's judgment the child does not have strabismus, nystagmus, or roving eye movements. Record '3' Suspect, if the findings are intermittent and not consistent for the eye in question. Record '4' if findings are untestable.

a. Strabismus (any kind):

Record Yes '1', is child has intermittent or persistent esotropia (in-turning) or exotropia (out-turning) resulting in ocular malalignment, esophoria or exophoria.

Assess the child's ability to move his eyes to the right, left, up, and down by moving a light from side to side, up and down in the midline, and diagonally across the bridge of the nose. The eyes should move in a smooth and unrestricted manner. Check for any of the following abnormal eye movements and record Yes '1'.

1. Esotropia or esophoria on the left: Left eye appears to deviate internally.
2. Esotropia or esophoria on the right: Right eye appears to deviate internally.
3. Alternating esotropia or esophoria: Child can fix with either eye, but the opposite eye deviates.
4. Exotropia or exophoria on the left: Left eye appears to deviate externally.
5. Exotropia or exophoria on the right: Right eye appears to deviate externally.
6. Alternating exotropia or exophoria: Child can fix with either eye but the opposite eye deviates.

b. Nystagmus

Persistent involuntary oscillation of eyes in any/ all fields of gaze

c. Roving Eye Movements

Record Yes '1' for Random eye movements - appears unable to fix/follow.

d. Tracks 180° (Record as 1, 2 or 4)

Have the child follow a bright toy or light across 180° of the field of vision. Record YES '1' if child is successful in following 180°, else record NO '2' or '4' if the child is untestable.

e. Vision:

Record separately for each eye.

The examiner should question the caretaker about the child's vision. If the child is prescribed glasses or contact lenses, the examiner should ask the caretaker how well the child sees with the glasses or contact lenses. If more than one applies, score the highest.

Record '1' if vision appears normal.

Record '2' if child wears or was prescribed corrective lenses.

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

Record '3' if child has an other abnormality affecting that eye other than a condition requiring corrective lenses but the impairment is not severe enough for the child to be considered blind in that eye.

Record '4' if child is considered to be blind but has some functional vision. For example, a condition that requires the child to have an object held directly in front of his/her face in order to see it, would be considered blind with some functional vision. This is consistent with a refraction definition of < 20-200 (legally blind).

Record '5' if child has no useful vision in that eye. This is consistent with a refraction definition of < 20-200 (legally blind).

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail the NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

The SUrfactant, Positive Airway Pressure and Pulse Oximetry Trial in Extremely Low Birth Weight Infants

ROP OUTCOMES AND TRACKING SUMMARY

Center: __ __ Site: ___ Network No. __ __ __ __ Birth No. ___ Mother's Initials: __ __ __

Record the data for each eye examination (in or outpatient) until both eyes are acute/final. Indicate when examinations switch from the NICU to a back-transfer hospital, or to outpatient

****** only answer these questions for the last eye exam entered***

This document is provided for reference purposes only. Persons with disabilities having difficulty accessing information in this document should e-mail NICHD FOIA Office at NICHDFOIARequest@mail.nih.gov for assistance.

This form should be completed for all children examined at the 18 + 4 month visit.

A. PHYSICAL EXAMINATION

1. Weight: ___ . ___ kg
2. Recumbent length: ___ . ___ cm
3. Occipital-frontal circumference: ___ . ___ cm

B. NEUROLOGIC EXAMINATION (performed by certified examiner)

1. Eye

	Right	Left
a. Strabismus (any kind)	____	____
b. Nystagmus	____	____
c. Roving Eye Movements	____	____

1 = Yes 2 = No 3 = Suspect 4 = Untestable

d. Tracks 180° (Record as 1, 2, or 4) ____ ____

1 = Yes 2 = No 4 = Untestable

	Right	Left
e. Vision:	____	____

1 = Normal
2 = Wears or was prescribed corrective lenses
3 = Other abnormality
4 = Blind some functional vision
5 = Blind no useful vision

2. Hearing

a. Was a Follow-up audiologic assessment completed since initial discharge to home? Y N

1) If NO, is consult pending for assessment? Y N

If YES, follow-up audiologic assessment completed, specify type of testing (2-4)

If the type of hearing exam is unknown **skip to question 4**

2) Visual Reinforcement Audiometry (VRA)? Y N

If Yes,

a. Right ___ b. Left ___ c. Sound field only___

Results: 1=Pass 2=Fail 3=Equivocal 4=Unknown

3) Auditory Brainstem Response (ABR)? Y N

If Yes,

a. Right ___ b. Left ___

1=Pass 3=Equivocal
2=Fail 4=Unknown

4) Unknown type of hearing test? Y N

If Yes,

a. Right ___ b. Left ___

1=Pass 3=Equivocal
2=Fail 4=Unknown

b. Hearing impaired (based on observation +/- history)? ____

1 = No apparent functional impairment **+/- amplification**
2 = Impairment **+/- amplification**

Note: If hearing is impaired and baby is enrolled in the Phototherapy Trial, complete the NF14 (18 Mo. Hearing Assessment Form).
